Dynamic Individuals, Static Neighborhoods: Migration and Earnings Changes in Poor Neighborhoods*

Andrew Garin, Ethan Jenkins, Evan Mast, and Bryan A. Stuart

September 2026

Abstract

Why do poor neighborhoods stay poor? Using administrative data linking residential histories to longitudinal earnings, we show that while many residents of poor neighborhoods have persistently low earnings and remain in concentrated poverty for extended periods, a large number also experience sizable earnings growth and move to richer areas. Estimates based on idiosyncratic, firm-specific pay changes show that part of this sorting is causal—earnings increases induce upward moves. On net, selective migration depresses the growth of poor neighborhoods' average earnings by roughly 60 percent and represents an underappreciated driver of the persistence of concentrated poverty.

> Once a slum has formed, the pattern of immigration that made it is apt to continue... Successful people, including those who achieve very modest gains indeed, keep moving out... they are quickly replaced by others who currently have little economic choice.
>
> —Jane Jacobs, *The Death and Life of Great American Cities* (1961)

1 Introduction

Concentrated neighborhood poverty has drawn attention from policymakers and researchers for over a century, driven by concerns about public health, quality of life, and educational and employment outcomes (Riis, 1890; President's Committee on Urban Problems, 1968; Jargowsky, 1997). Poor neighborhoods are also central to research on neighborhood effects (Kling et al., 2007), economic opportunity (Chetty et al., 2026), and place-based policy (Busso et al., 2013).

In the modern United States, a central fact is that poor neighborhoods tend to stay poor (Cortright and Mahmoudi, 2014; Malone and Redfearn, 2018). However, the drivers of this persistence are not well understood. Jacobs (1961) describes a dynamic mechanism, in which many people in poor neighborhoods improve their circumstances and then tend to exit the neighborhood. Wilson (1987) developed this argument into the central account of postwar concentrated poverty, emphasizing the departure of middle-class families from inner-city Black neighborhoods. However, this story of dynamic individuals and static neighborhoods has proven difficult to fully assess because it requires longitudinal data on individual earnings and migration. Moreover, this account runs counter to recent work emphasizing non-monetary barriers to exit from poor neighborhoods (Desmond, 2016; Christensen and Timmins, 2022; Bergman et al., 2024), as well as evidence of multi-generational spells in concentrated poverty (Sharkey, 2013).

We use new data to study individual earnings changes and migration in poor neighborhoods and how they in turn shape neighborhood outcomes. We begin by showing that poor neighborhoods contain diverse individual trajectories. Consistent with work emphasizing barriers to exit, many residents have persistently low earnings and remain in concentrated poverty for extended periods. However, a sizable group experiences significant earnings growth and moves to richer neighborhoods at a high rate, much as Jacobs and Wilson describe. The two strands of literature

thus describe different types of people who coexist in the same neighborhoods. We then show that Jacobs's dynamic mechanism is quantitatively important: if poor neighborhoods maintained their initial set of residents, their average earnings would grow more than twice as rapidly. The same forces imply that place-based policies that raise individual earnings will only partially translate into higher average earnings for the neighborhoods those individuals initially live in.

To guide our empirical analysis, we first develop a model of household income and neighborhood choice to characterize how individual choices aggregate into neighborhood-level outcomes. The empirics are built on a large panel that pairs detailed individual demographic characteristics with longitudinal information on earnings and migration. We construct this panel by linking adult respondents to the American Community Survey (ACS) between 2005 and 2013 to newly available address history data from the Census Bureau and the Longitudinal Employer-Household Dynamics (LEHD) data. We define high-poverty neighborhoods as census tracts with a poverty rate over 30 percent, roughly the poorest decile of tracts.

We begin by describing earnings dynamics among residents of poor neighborhoods. Prior work has shown that people with low earnings at a point in time generally have high earnings volatility and rapid subsequent growth (Bane and Ellwood, 1986; Abowd et al., 2018; Guvenen et al., 2021), but this may not be the case in very poor neighborhoods if the environment depresses earnings growth, perhaps through limited commuting access or job referral networks (e.g., Bayer et al., 2008). We find that people living in high-poverty neighborhoods at baseline have very similar future earnings growth rates to people in less poor areas, including a long right tail of large increases.

We then describe general migration patterns in poor neighborhoods. Transition rates are high, with 51 percent of adults exiting their baseline census tract over the following ten years. Moreover, 78 percent of moves are to tracts below our high-poverty threshold, including many tracts with much lower poverty rates.[1] Next, building on Quillian (2003), we calculate for each person living

[1]These results generalize similar findings that have appeared in small survey samples (Gramlich et al., 1992; Massey et al., 1994; South and Crowder, 1997) and specific contexts such as housing assistance programs (Kling et al., 2007; Staiger et al., 2024) and gentrification (Ellen and O'Regan, 2011; Brummet and Reed, 2021). Sampson and Sharkey (2008) and Coulton et al. (2012) produce similar estimates using multi-wave surveys in particular cities.

in a high-poverty tract in the baseline year how many of the subsequent ten years they spend in a poor tract. The distribution is bimodal. About 54 percent live in concentrated poverty for all of the next ten years, while 31 percent spend five or fewer years in poor neighborhoods. Subgroup estimates reveal that the bimodality is generated by distinct, observably different groups of people. For example, 31 percent of those under age 35 spend all of the following ten years in similarly poor neighborhoods, versus 71 percent of individuals over age 65. Renters have low exposure, while homeowners and public housing residents tend to experience long spells.

Our final set of individual-level results establishes the last link in the Jacobs-Wilson story: people with high earnings growth tend to leave. Among individuals beginning in a high-poverty tract, those whose real annual earnings increase by $20,000 over an eight-year period are 11 percentage points more likely to have exited concentrated poverty by the end of this period than those who experience no earnings growth, and they end up in tracts with $4,700 higher median income. Entry to high-poverty tracts exhibits the opposite relationship with earnings.

The policy implications of the relationship between earnings growth and migration depend on whether it is causal. Individuals with rising incomes may move out of poor neighborhoods due to correlated preference shifts (for example, life-cycle patterns such as starting a family) rather than a causal effect of earnings growth *per se*. To identify the causal impacts of earnings changes, we build on the design in Rose and Shem-Tov (2023) to examine the effects of idiosyncratic, firm-level pay shocks, which we infer using changes in coworker earnings following Koustas (2018) and Ganong et al. (2020). We find that a shock that increases annual household earnings four to eight years later by 1.27 log points leads to an increase in tract median income of 0.18 log points, implying an elasticity of 0.14. Individuals have a clear tendency to move towards higher-income neighborhoods after positive earnings shocks, and the implied elasticity is highest for renters, those with children, and those initially in poor tracts. However, while earnings changes can explain a large portion of residential mobility for some groups, other factors are also important. In particular, although causal elasticities are larger in high-poverty neighborhoods than elsewhere, earnings growth accounts for only a small portion of the high exit rates from these areas.

Together, the individual results suggest that some people in poor neighborhoods move up and out, but many others follow a flatter trajectory. We use a "pass-through" statistic developed in the conceptual framework to bring these individual-level patterns together and quantify their contribution to the persistence of concentrated poverty. Specifically, we take the ratio of the growth in average earnings among the cohort of people who *start* in a poor neighborhood (regardless of where they live later) and the growth among the people who *live* in those neighborhoods in each subsequent year. The baseline cohort's earnings increase by 26 percent over the subsequent ten years, similar to cohorts beginning in less poor neighborhoods. However, earnings of contemporaneous residents grow by only 11 percent, a pass-through of 0.43. The leakage comes from selective exit: those who have left by year ten earn $6,900 more than those who remain. Entrants are positively selected relative to stayers, which slightly offsets the strong selective exit.

This pass-through estimate describes the status quo, but it is not a structural parameter. In our final exercise, we consider the pass-through rate of a hypothetical policy that increases the earnings of individuals in poor neighborhoods. Back-of-the-envelope calculations point to values between 0.28 and 0.48, with most leakage due to high baseline migration rather than to program-induced moves. Relatedly, high earnings growth among initial residents means that reducing the exit rate is itself a policy lever, as suggested by Jacobs (1961)'s proposal of "unslumming the slums, by creating conditions aimed at persuading residents to stay by choice over time." Raising pass-through in high-poverty neighborhoods to the level observed in medium-poverty areas would increase their mean earnings growth by 44 percent.

Our primary contribution is to the literature on concentrated neighborhood poverty.[2] Our results reconcile seemingly conflicting perspectives on poor neighborhoods (e.g., Jacobs, 1961; Wilson, 1987; Sharkey, 2013; Bergman et al., 2024) by using new data to measure individual trajectories and show that there are large numbers of both upwardly mobile and "stuck" individuals in poor

[2] A long tradition of qualitative research has examined disadvantaged neighborhoods or "slums" (Whyte, 1943; Liebow, 1967; Suttles, 1968). Researchers have specifically studied kinship networks, neighborhood norms, and the public housing environment (Rainwater, 1970; Anderson, 1990; Venkatesh, 2000). Related work has considered determinants of migration decisions in poor neighborhoods, particularly eviction and housing instability (Sharkey, 2012; Skobba and Goetz, 2013; DeLuca et al., 2019).

neighborhoods at any point in time. This advance is possible because we assemble data that both contains longitudinal earnings and migration records and has the sample size and demographic detail needed to precisely measure differences across subgroups. In addition, we show that upwardly mobile individuals, who have been emphasized but not well measured in the seminal work of Jacobs and Wilson, create a substantial divergence between the earnings growth of poor neighborhoods and their initial residents. This dynamic mechanism of persistence is substantially different than a purely static story, and it points to a distinct set of policy levers.

Our paper also contributes to the broader literature that studies how households make location choices, often using structural models of migration in which individuals trade off different neighborhood characteristics (e.g., Epple and Sieg, 1999; Bayer et al., 2007; Galiani et al., 2015; Bayer et al., 2016; Davis et al., 2021; Ferreira and Wong, 2023) or housing policy experiments that provide subsidies or other support (e.g., Kling et al., 2007; Chetty et al., 2016). This literature generally does not focus on the relationship between migration and earnings changes, often because of a lack of data.[3] We provide evidence on the importance of this relationship, along with empirical moments that can help discipline quantitative models that include earnings changes.

Finally, our analysis connecting individual-level dynamics to neighborhood-level outcomes adds to research on how neighborhood economic and demographic composition evolves over time (e.g., Card et al., 2008; Malone and Redfearn, 2018; Couture and Handbury, 2020). These papers generally study neighborhood-level outcomes and lack individual panel data. We show that, in the case of concentrated poverty, large individual earnings dynamics and frequent migration are essential components of the process that produces persistent neighborhood-level outcomes.

2 Conceptual Framework

In this section, we present a simple model that highlights the factors that drive residential mobility and then examine how individual mobility ultimately shapes the evolution of neighborhoods. This

[3] A notable exception is Bilal and Rossi-Hansberg (2021), who develop a dynamic model of individual location choice and estimate the effect of mass layoffs on movement across French municipalities.

framework helps to motivate and structure the empirical analysis that follows.

2.1 Household Neighborhood Choice

We first consider the determinants of individual residential mobility using a stylized model of neighborhood choice. Household i in demographic group g chooses a neighborhood j with time-invariant quality $q_j > 0$ and rent r_j, where rent is increasing in quality. The household has exogenous earnings y_i that exceeds rent in all neighborhoods, and spends $c_{ij} = y_i - r_j$ on numeraire consumption. Indirect utility from living in neighborhood j is

$$V_{ij} = \ln(y_i - r_j) + \left(\beta_g + \delta_g \ln y_i\right) \ln(q_j) + a_{ij} + \varepsilon_{ij}. \tag{1}$$

This specification of preferences allows for both a baseline taste for neighborhood quality $\beta_g > 0$ as well as a term $\delta_g > 0$ that captures the complementarity between earnings and neighborhood quality, both of which may differ across groups (e.g., households with and without children). The term a_{ij} describes a non-earnings match component, which can reflect factors like family and social ties, discrimination, and moving costs. We refer to $a_i = (a_{i1}, \ldots, a_{iJ})$ as a household's match preferences, though it can also reflect constraints. The shock ε_{ij} is i.i.d. Type-I Extreme Value with group-specific scale σ_g. Match preferences enter choice probabilities as parameters, and we study how changes in them affect mobility. The shock ε_{ij}, by contrast, generates closed-form expressions for choice probabilities and is not an object of interest for comparative statics.

In this set-up, we can study how changes in earnings or match preferences shape residential mobility by analyzing comparative statics on expected neighborhood quality. For households with earnings y_i and match preferences a_i, expected quality is

$$\ln(q_i) \equiv \ln(q(y_i, a_i)) = \sum_j \Pr(j \mid y_i, a_i) \ln(q_j),$$

where $\Pr(j \mid y_i, a_i)$ is the probability of choosing neighborhood j given y_i and a_i. Because q_j is fixed, any change in $\ln(q_i)$ reflects migration.

A household's expected neighborhood quality can evolve because of changes in earnings or match preferences. The total derivative of expected neighborhood quality is:

$$d \ln q_i = \underbrace{\frac{\partial \ln q_i}{\partial \ln y_i} d \ln y_i}_{\text{earnings}} + \underbrace{\frac{1}{\sigma_g} \operatorname{Cov}\big(\ln q_j,\, da_{ij} \big)}_{\text{match preferences}}, \tag{2}$$

where the covariance is weighted by the household's neighborhood choice probabilities. The first term reflects moves induced by earnings growth, and it depends on both the sorting elasticity $\eta_{ig} \equiv \partial \ln q_i / \partial \ln y_i$ and the change in earnings $d \ln y_i$. The second reflects moves induced by shifts in match preferences. All derivations are in Appendix A.

The sorting elasticity can be further decomposed into two channels:

$$\eta_{ig} = \frac{1}{\sigma_g} \Bigg[\underbrace{\delta_g \operatorname{Var}(\ln q_j)}_{\text{complementarity channel}} + \underbrace{\operatorname{Cov}\left(\ln q_j,\, \frac{y_i}{y_i - r_j} \right)}_{\text{budget-constraint channel}} \Bigg] > 0. \tag{3}$$

Under the *complementarity channel*, higher earnings raise the weight $\delta_g \ln y_i$ on quality, making better neighborhoods more attractive. The effect is proportional to the variance of neighborhood quality among the household's likely choices, since there are greater potential gains when neighborhoods differ more. Under the *budget-constraint channel*, earnings increases make higher-quality neighborhoods, which have higher rents, more affordable. These more expensive neighborhoods are where the marginal utility of consumption is highest (under our assumption that utility is concave in consumption). This channel is stronger in cities where the quality-rent gradient is steeper. Both channels are positive, so earnings growth moves households to better neighborhoods.

Separating the drivers of migration into these channels illustrates why residential mobility might differ across groups. First, groups differ in how much their earnings grow ($d \ln y_i$): those with more earnings mobility upgrade more. Second, groups differ in the sorting elasticity η_{ig}. This response is larger for lower-earnings groups—for whom $y_i/(y_i - r_j)$ varies more sharply across neighborhoods, leading to a stronger budget-constraint channel—and for groups with higher quality-earnings complementarity δ_g, such as parents. Third, changes in match preferences,

$\frac{1}{\sigma_g}\text{Cov}(\ln q_j, da_{ij})$, might evolve differently as attachments, moving costs, and constraints change. The dispersion of idiosyncratic preferences, σ_g, also dampens migration responses.

2.2 From Household Choice to Neighborhood Evolution

When the sorting elasticity is positive or changes in match preferences are correlated with earnings changes, a neighborhood may remain persistently poor even when its initial residents experience substantial earnings growth due to the "leakage" of higher-earning residents. We now describe the relationship between household and neighborhood earnings dynamics in the presence of selective migration.

To be concrete, we focus on high-poverty neighborhoods. Let $d_{it} \in \{0, 1\}$ indicate residence in a high-poverty neighborhood at time t. Average earnings among residents of high-poverty neighborhoods at time t is $\bar{y}_t^{\text{place}} \equiv E[y_{it} \mid d_{it} = 1]$. Average earnings of the cohort of individuals who reside in high-poverty neighborhoods at baseline (regardless of where its members later live) is $\bar{y}_t^{\text{cohort}} \equiv E[y_{it} \mid d_{i0} = 1]$. The two measures coincide at $t = 0$ but diverge afterward only through migration. The place-level average equals the initial cohort average minus terms reflecting the earnings of exiters relative to stayers and stayers relative to entrants:

$$\bar{y}_t^{\text{place}} = \bar{y}_t^{\text{cohort}} \underbrace{- \pi_t^{\text{exit}} \left(\bar{y}_t^{\text{exit}} - \bar{y}_t^{\text{stay}} \right)}_{\text{exit channel}} \underbrace{- \pi_t^{\text{entr}} \left(\bar{y}_t^{\text{stay}} - \bar{y}_t^{\text{entr}} \right)}_{\text{entrant channel}}. \tag{4}$$

This decomposition relies on a partition of households into *stayers* ($d_{i0} = d_{it} = 1$), *exiters* ($d_{i0} = 1,\ d_{it} = 0$), and *entrants* ($d_{i0} = 0,\ d_{it} = 1$), with mean earnings $\bar{y}_t^{\text{stay}}$, $\bar{y}_t^{\text{exit}}$, and $\bar{y}_t^{\text{entr}}$. The share of the initial cohort that has left by time t is $\pi_t^{\text{exit}} \equiv \Pr(d_{it} = 0 \mid d_{i0} = 1)$, while the share of current residents who arrived after baseline is $\pi_t^{\text{entr}} \equiv \Pr(d_{i0} = 0 \mid d_{it} = 1)$.

We use equation (4) to define a key quantity that we estimate empirically: the *pass-through* of household earnings growth to the neighborhood as of time t:

$$\rho_t \equiv \frac{\bar{y}_t^{\text{place}} - \bar{y}_0^{\text{place}}}{\bar{y}_t^{\text{cohort}} - \bar{y}_0^{\text{cohort}}} = 1 - \frac{\pi_t^{\text{exit}} \left(\bar{y}_t^{\text{exit}} - \bar{y}_t^{\text{stay}} \right) + \pi_t^{\text{entr}} \left(\bar{y}_t^{\text{stay}} - \bar{y}_t^{\text{entr}} \right)}{\bar{y}_t^{\text{cohort}} - \bar{y}_0^{\text{cohort}}}. \tag{5}$$

Pass-through represents the ratio of growth in neighborhood average earnings to the growth in incumbent average earnings. This is not a structural parameter, but rather a characterization of the gap between resident earnings growth and neighborhood change at a given point in time. A pass-through of 1 means that average earnings in poor neighborhoods grow at the same rate as the average earnings of their baseline cohort.[4]

To develop intuition, consider the case where the entry rate adjusts to equal the exit rate ($\pi_t^{\text{exit}} = \pi_t^{\text{entr}}$) and neighborhood population is constant. In this steady state, equation (5) simplifies to

$$\rho_t^{SS} = 1 - \frac{\pi_t^{\text{exit}}(\bar{y}_t^{\text{exit}} - \bar{y}_t^{\text{entr}})}{\bar{y}_t^{\text{cohort}} - \bar{y}_0^{\text{cohort}}}. \tag{6}$$

While this accounting identity holds regardless of the underlying individual behavior, the model in Section 2.1 can be used to connect pass-through to fundamental parameters. In particular, one can show that, first, whenever the sorting elasticity η_{ig} is positive and entrants to poor neighborhoods are negatively selected on earnings, pass-through is less than 1. Second, when η_{ig} is larger or earnings growth is more strongly correlated with preference shifts towards richer neighborhoods, exiters are more positively selected and pass-through is smaller. Third, holding average baseline cohort earnings growth fixed, if earnings improvements are more concentrated among a subset of residents, pass-through is lower because individuals with larger gains are more likely to exit.

In our empirical analysis, we directly estimate pass-through as observed in the data, decomposing it into the exit and entrant channels in equation (5). We also consider how the pass-through rate of hypothetical policies that increase the earnings of initial residents depends on underlying causal parameters and distributional impacts of the policies.

[4]Note that pass-through is well-defined only when the initial cohort experiences positive earnings growth.

3 Data and Background

3.1 Data Sources

We draw longitudinal address information from the Census Bureau's Master Address File-Auxiliary Reference File (MAFARF). This data includes the geolocated housing unit of residence for the near-universe of adults in each year (our vintage includes 2000–2021), which is derived from federal tax, health, and housing records.[5] We use these data to identify each individual's (2010 vintage) census tract in each year, which we use as our definition of neighborhood throughout the paper. We validate the MAFARF using decennial census and ACS data, as discussed below.

We use earnings data from the Census Bureau's Longitudinal Employer-Household Dynamics (LEHD) database. Our LEHD extract contains 25 states and at least the 2000 to 2021 time period for all states. The data includes quarterly employment and earnings for individuals whose employers participate in unemployment insurance, as well as employer information, such as industry NAICS code. The included states are representative of the country in terms of population, region, and demographic composition.[6] We adjust earnings (and all other dollar-valued variables used in the analysis) to 2019 dollars using the Consumer Price Index.

Individual and household demographics are mostly drawn from the ACS, which is an annual survey spanning roughly three percent of households. For each individual, we observe demographics including age, sex, education, and race/ethnicity. At the household level, we observe renter status and total household income. In addition, the ACS contains self-reported measures of earnings, wages, and hours worked that supplement the LEHD data. We also use the Department of Housing and Urban Development's Tenant Rental Assistance Certification System to identify households living in public housing or receiving voucher assistance.

Finally, we construct tract characteristics by aggregating ACS responses. We calculate poverty

[5]Graham et al. (2017) and Sullivan and Genadek (2024) discuss the administrative data sources used to construct the MAFARF and provide some basic validation.

[6]Our LEHD extract consists of Arizona, California, Colorado, Connecticut, Delaware, Indiana, Iowa, Maine, Maryland, Massachusetts, Nevada, New Jersey, New Mexico, North Dakota, Ohio, Oklahoma, Pennsylvania, South Carolina, South Dakota, Tennessee, Utah, Virginia, Washington, Wisconsin, and Wyoming.

rates, median household incomes, and median home values using the 2005 to 2009 waves of the ACS, which coincides with the start of our sample period. We use time-invariant measures of neighborhood characteristics to ensure that they are not influenced by the migration that we study.

3.2 Sample Construction

We combine these data sources to create a large and representative panel of individuals containing information on demographics, residential location, and labor market outcomes. The initial sampling frame consists of respondents to the 2005 to 2013 waves of the ACS. We restrict to individuals who, at the time they were sampled in the ACS, were at least 25 years old, not full-time students or in the armed forces, not the child of the household head, and not living in group quarters or a tract in which more than 20 percent of the population is between the ages of 18 and 25.[7]

We define the baseline year for each individual as the year that they were sampled in the ACS.[8] We then merge in longitudinal address information from the MAFARF for the five years prior to and ten years following the baseline.[9] For people living in a state included in our LEHD extract in the baseline year, we then add information on employment and earnings.

Throughout the paper, we group tracts into broad categories based on their poverty rate in the 2005–2009 ACS. The categories are 0 to 10 (roughly the bottom half of tract poverty rates), 10 to 20 (percentiles 50 to 75), 20 to 30 (percentiles 75 to 90), and 30 to 100 percent (the highest decile). For robustness, we also use population-weighted quintiles of median household income (defined nationally) to define neighborhood categories in some exercises.

Depending on the exercise, we use different subsamples of this overarching panel. Defining these samples separately highlights that we measure migration for a nationwide sample, while our analysis of earnings is limited to states in the LEHD extract and focuses on individuals well below common retirement ages. Appendix Table A.1 shows descriptive statistics for each sample.

[7]This restriction, which affects about one percent of census tracts, is intended to remove neighborhoods with high amounts of college student housing from the sample.

[8]In the event that an individual was sampled twice, we use their first response.

[9]Graham et al. (2017) show that 94 percent of 2012 ACS respondents appear in the MAFARF.

Migration sample: For results that do not incorporate any earnings or employment information, we use the matched ACS-MAFARF data for the full U.S. In order to include ten follow-up years, we include only respondents to the 2005 to 2011 ACS waves. This sample consists of 13.2 million unique individuals, including 670,000 who live in high-poverty neighborhoods in the baseline year.

Earnings sample: For results on earnings dynamics or the relationship between earnings and migration, we use the matched ACS-MAFARF-LEHD data. We include the 2005 to 2013 ACS waves and use an eight-year follow-up window.[10] We drop individuals who do not live in a state in our LEHD extract in the follow-up period, as well as individuals who were over age 55 at the time of the ACS survey. The resulting sample contains 3.6 million unique individuals, including 164,000 in high-poverty tracts at baseline. In some exercises, we define people with earnings below $4,000 in the LEHD as nonemployed.

3.3 High-Poverty Neighborhoods

We are especially interested in high-poverty neighborhoods, defined as census tracts with poverty rates over 30 percent.[11] This is approximately the poorest decile of tracts, and they have similar composition to the impoverished areas that were targeted by the federal Empowerment Zone (EZ) program in the 1990s. Concentrated poverty of this sort is highly persistent (Cortright and Mahmoudi, 2014). Among tracts where the poverty rate exceeded 30 percent in 1990, 86 percent had poverty above 20 percent in 2020, and only 7.7 percent saw their median income rise above the median tract in their metropolitan area. Alternatively, although Busso et al. (2013) find that the EZ program had positive effects on employment and incomes, the average EZ tract had a poverty rate of 35 percent in 2020.

No single race or ethnic group dominates the set of poor neighborhoods. In the 2010 census, 29 percent of residents were non-Hispanic White, 29 percent were non-Hispanic Black, and 36 percent

[10] We make this slight change from the selection criteria of the migration sample to reduce the share of observations that begin during the peak of the Great Recession.

[11] Prior literature has generally defined high-poverty neighborhoods as those where the poverty rate exceeds 30 (Wilson, 1987) or 40 percent (Jargowsky, 1997; Kneebone et al., 2011).

were Hispanic. However, these nationwide averages overstate the degree of racial diversity within individual high-poverty tracts. Ninety percent have a racial or ethnic majority, split roughly evenly between White, Black, and Hispanic majorities.

Similarly, not all residents of high-poverty neighborhoods are poor. Thirty-one percent make over $25,000 (approximately the national median of individual earnings). Labor force attachment is lower in poor neighborhoods: the prime-age (25–54) employment rate is 61 percent versus an average in less-poor neighborhoods of 78 percent. Differences in the housing market are consistent with these income patterns, with 58 percent of housing units in poor neighborhoods occupied by renters (versus an average of 31 percent in the remainder of the sample) and 8.2 percent of renter households using a housing choice voucher (versus an other-neighborhood average of 4.0 percent). The overall picture from these statistics is quite similar to the analysis of Jargowsky (1997) using the 1990 census, suggesting that the important patterns are stable over time.

4 Earnings Dynamics in Poor Neighborhoods

Do residents of poor neighborhoods experience meaningful earnings growth? The combination of the LEHD and MAFARF data allows us to address this question directly, with the caveat that it only incorporates formal wage and salary employment. Unlike most of the earnings dynamics literature, we do not impose a minimum earnings threshold in our analysis, as the prevalence of low earners and non-employed individuals may be an important feature of poor neighborhoods.

We begin by describing labor force transitions over an eight-year period among people who lived in different types of neighborhoods in the baseline year. Table 1 shows that residents of high-poverty tracts are modestly more likely to be nonemployed in both periods (30.6 vs. 26.2 percent in the lowest poverty tracts), but the more notable pattern is that they are substantially more likely to transition between employment and nonemployment (in either direction).

Figure 1 further shows the full distribution of eight-year earnings changes for each neighborhood type.[12] The histograms are surprisingly similar, with comparable right tails and large shares

[12]To distinguish between employed individuals with little earnings change and those who are consistently nonem-

experiencing modest gains. Notably, 13 percent of residents in the poorest neighborhoods experience real earnings growth over $20,000, likely driven in part by the high frequency of transitions into employment in these areas.

We more formally examine differences in mean earnings growth across individuals in different neighborhoods in Table 2. We first regress eight-year individual earnings changes—in levels in Panel A and arc percent in Panel B—on indicator variables for individuals' baseline neighborhood poverty category.[13] Residents of high-poverty neighborhoods experience real earnings growth of $2,700 on average. Mean earnings increases in levels are higher in less-poor neighborhoods, but much of this gap can be explained by differences across individuals in race and ethnicity, age, and baseline education (column 3). The comparison of growth rates in Panel B is especially notable: the average arc percent change is quite similar across neighborhoods, and the modest remaining gap between the highest- and lowest-poverty neighborhoods narrows to 1.6 percent with individual controls. When we restrict to people with moderate labor force attachment, differences across neighborhood types vanish (Appendix Table A.2)—consistent with the residual gap in earnings growth rates being explained by changes in employment status, not differences in wage trajectories conditional on working.

Overall, our results suggest that poor neighborhoods contain a substantial number of upwardly mobile individuals. This is consistent with prior work finding that poor neighborhoods do not significantly worsen adults' labor market outcomes (Kling et al., 2007), and it provides the individual improvements at the root of Jacobs's account of concentrated poverty.

5 Migration in Poor Neighborhoods

This section studies residential mobility in poor neighborhoods. We first show that their residents move frequently, usually to lower-poverty areas. We then study longitudinal exposure to high-poverty neighborhoods and find both a bimodal distribution and significant variation across

ployed, we omit the latter from the histogram and report their share in the corner of each panel of the figure.

[13]The arc percent change is the percent change using the average of the start and end points as the denominator. This allows us to calculate proportional earnings growth among people with zero earnings at the start or end point.

demographic groups.

5.1 Migration Rates

Figure 2 plots the probability that an individual lives in their baseline tract in each of the ten subsequent years, separately for individuals beginning in different types of neighborhoods. Among all individuals, 43 percent of people live in a different tract at the end of the ten-year period. Panel A shows that rates of out-migration are elevated in high-poverty neighborhoods, where over 10 percent of individuals move out of their tract in year one and 51 percent live in a different tract ten years later. Panel B shows a similar pattern of higher migration rates out of poorer neighborhoods when classifying tracts based on their median income.[14] These results generalize a number of recent estimates that focused on specific groups of people and neighborhoods.[15]

One potential explanation for elevated migration rates out of poorer neighborhoods is that their residents simply belong to demographic groups who have higher migration rates regardless of where they live, such as younger individuals. To examine this, Appendix Table A.3 reports regressions in which the dependent variable is an indicator for moving out of one's baseline tract over an eight-year period. Comparing the raw cross-neighborhood differences in mobility rates in column 1 to the within-CBSA, demographics-adjusted differences in column 3, resident composition does not appear to drive the baseline differences in mobility rates across neighborhoods.

The economic significance of these moves depends on the types of neighborhoods people move to. If individuals from poor neighborhoods simply move to other poor neighborhoods, there may be little improvement in the conditions or opportunities they face. We report the full matrix of transitions across neighborhood types over an eight-year period in Table 3. Transitions to better neighborhoods are common: 36.5 percent of people who begin in the highest poverty category

[14] In Appendix Figure A.1, we replicate Figure 2 using tract locations drawn from the 2005–2009 ACS surveys and the 2010 decennial census rather than the MAFARF. Estimates are quite similar, consistent with the MAFARF capturing migration accurately.

[15] Brummet and Reed (2021) find that 52.3 percent of the residents of initially low-income, central city tracts in 2000 had moved by the time they were observed in 2010–2014. Staiger et al. (2024) study census block groups containing public housing buildings and find that just under 20 percent change block groups in the baseline year, increasing to 65 percent after ten years. Frenette et al. (2004) find a one-year exit rate of 13.8 percent in low-income census tracts in large Canadian cities.

transition to a tract with a poverty rate below 30 percent, implying that 78 percent of migrants from these tracts move to lower-poverty neighborhoods. The small relative size of the highest-poverty category (roughly 10 percent of tracts and 5 percent of individuals in the sample) mechanically increases its out-migration rate relative to other categories, but in Panel B we similarly see that 17.8 percent of the bottom tract income quintile transitions to the third quintile or above.[16] Individuals also move from richer to poorer neighborhoods, although these types of moves are less common. This asymmetry is consistent with both individuals increasing neighborhood quality over the lifecycle and slow population growth in poor neighborhoods.[17]

Several studies using the PSID also document high migration rates out of poor neighborhoods, but are limited by small sample sizes of hundreds or a few thousand individuals (Gramlich et al., 1992; Massey et al., 1994; South and Crowder, 1997).[18] The modern administrative data allows us to measure migration with less noise and consider more granular neighborhood categories. We also measure transitions directly over longer time horizons, whereas prior work observes only one-year transitions, which imply exaggerated long-run mobility.[19]

5.2 Longitudinal Exposure to Concentrated Poverty

We next quantify *longitudinal* exposure to concentrated poverty in Table 4, separately for a number of demographic groups. For this analysis, we take the set of people living in their baseline year in tracts with poverty rates over 30 percent and calculate the share of the following ten years that they

[16] In Appendix Figure A.2, we create a variant of Table 3 using both the MAFARF and tract locations drawn from the ACS and 2010 decennial census. The different data sources again yield very similar results.

[17] Table 3 implies that individuals starting in the bottom three quintiles of tract income are more likely to move to a different income quintile than individuals starting in the top quintile. Appendix Table A.5 shows that this difference survives controlling for CBSA fixed effects and individual demographics.

[18] Gramlich et al. (1992) report that 9.9 percent of poor residents of tracts with over 30 percent poverty move to a tract below that poverty threshold in a given year, while South and Crowder (1997) find an 8.0 percent annual exit rate using a 20 percent poverty cutoff. These are both close to our estimate of 8.8 percent (using a 30 percent cutoff). South and Crowder (1997) find that residents of poor tracts are more likely to relocate to another poor tract than to a non-poor one (12.5 versus 8.0 percent annually), whereas we find that the large majority of movers from the highest-poverty tracts reach lower-poverty neighborhoods. This difference could be driven by their lower tract poverty threshold, differences in sample period, or sampling error.

[19] In our data, the one-year out-migration rate from the highest-poverty category is 8.8 percent (Appendix Table A.4). Extrapolating this forward as a Markovian transition probability implies an eight-year out-migration rate of 52.1 percent ($= 1 - (1 - 0.088)^8$), which is much higher than our direct estimate of 36.5 percent (Table 3).

spend in tracts above this threshold.[20] We continue to freeze tract poverty at 2005–2009 levels and consider the role of neighborhood change separately.

The first row of Table 4 shows that the overall distribution of exposure to high-poverty neighborhoods is bimodal. Thirty-one percent of individuals living in a high-poverty tract at baseline spend no more than 5 out of the next 10 years in concentrated poverty, while 54 percent experience a full 10 years of exposure. The average individual has 7.2 years of exposure. Exits from concentrated poverty typically entail moves to significantly lower-poverty neighborhoods—the average person who has exited concentrated poverty by year 5 lives in a tract with poverty rate 24 percentage points lower than their baseline tract. These results are consistent with the existence of both a large mass of people who are "stuck in place" (Sharkey, 2013) and a significant group who is much more mobile.

The lower rows of Table 4 show subgroup estimates, shedding light on what predicts short versus long spells. Age is the most important factor: people aged 25–34 at baseline spend an average of 5.5 years in concentrated poverty, compared to 7.6 years for those aged 45–54 and 8.5 years for those over 65. This gradient is consistent with younger residents experiencing more change in their earnings and life circumstances, while older residents may have both less incentive to move and higher moving costs. Surprisingly, exposure varies less by race, with Black (7.3 years) and Hispanic (7.5 years) individuals having only slightly higher exposure than White individuals (6.8 years). Households where children are present see 6.8 years of exposure, versus 7.5 for other households, including a particularly low 6.1 years among adults under 40 who live in a household with children. We cannot infer the causal effects of having children on exposure to concentrated poverty from these differences, but they suggest that young children, who Chetty et al. (2016) find are most negatively affected by concentrated poverty, see below-average exposure.

Housing tenure, which shapes moving costs, also matters. Homeowners have the highest average exposure to concentrated poverty at 8.0 years, potentially reflecting high transaction costs and local attachments, and public housing residents are nearly as persistent at 7.9 years. Voucher hold-

[20] We include only individuals who appear in the MAFARF in at least 8 follow-up years and we proportionally adjust exposure of those observed in fewer than 10 years.

ers, whose subsidies travel with them, show lower exposure at 6.7 years, and unsubsidized renters have the lowest at 6.1 years. Labor force participation also strongly predicts exposure: workers are 12 percentage points more likely to have five or fewer years of exposure. However, average exposure is nearly identical for the poor and non-poor, likely because poverty status is highly correlated with age and household composition.[21]

Finally, differences emerge across geographies. Exposure decreases slightly as CBSA size increases, potentially reflecting differences in the size and variance of the neighborhood choice set. Consistent with our model's prediction, the slope of the neighborhood quality-rent curve appears to be important. We stratify individuals who live in CBSAs according to the difference between the log of average rents in the CBSA's high-poverty tracts and its tracts with 20 to 30 percent poverty. In areas where this gap is over 0.20, individuals have an additional year of poverty exposure and are 10 percentage points less likely to exit within five years.

For individuals who do *not* move, changes in neighborhood conditions can also affect long-run exposure to concentrated poverty. Column 6 shows the share of people who stayed in their baseline tract for ten years and saw the tract's poverty rate fall below 25 percent in the 2015–2019 ACS. These are "stayers" whose neighborhood poverty rate fell by at least 5 percentage points during the sample period. This group represents 12.7 percent of all individuals who start in a high-poverty neighborhood and nearly 25 percent ($= 0.127/0.538$) of all people with ten years of exposure. The average person in this group sees their tract poverty rate fall by 15 percentage points.[22]

The results in Table 4 replicate and expand upon earlier analyses by Quillian (2003), who uses the PSID and similarly finds a bimodal exposure distribution and a substantial low-exposure

[21]These results focus on how demographics correlate with exit from poor neighborhoods, but studying entrants is also informative. Appendix Table A.6 shows that the people who enter high-poverty neighborhoods in a given year have similar demographic characteristics to the people who exit, while stayers are substantially older, more likely to own their home, and less likely to be employed. This is again consistent with the existence of a relatively young and mobile group that passes through these neighborhoods and looks markedly different from long-term residents. However, exiters also have somewhat higher earnings, income, and employment than entrants. This is consistent with individuals using poor neighborhoods to smooth consumption over low-income periods of the lifecycle or idiosyncratic shocks, as we explore further below.

[22]These estimates may raise concerns that incorporating neighborhood change would significantly alter our exposure estimates. To investigate this issue, we calculate the average tract poverty rate experienced by individuals in the Table 4 sample using the 2005–2009 ACS poverty rates and the 2015–2019 rates. The figure is 31.9 percent with the earlier survey and 28.0 percent with the later, suggesting that neighborhood change slightly reduces exposure.

group.[23] The scale of the administrative data allows us to extend this analysis to more subgroups and with greater precision. We find that age and renter status, which the earlier paper does not study, are very important, while the gaps between Black and White individuals emphasized in Quillian (2003) are much smaller in our analysis.[24]

6 Earnings Changes and Migration

Our last set of individual results concerns the relationship between earnings growth and residential mobility. We begin with descriptive evidence illustrating that individuals tend to move to higher-income neighborhoods when their earnings rise, especially when coming from poor neighborhoods. This links our first two sets of results: the people who leave poor neighborhoods are disproportionately those who improved their economic circumstances. We then use a research design based on idiosyncratic, firm-specific changes in pay to better establish the connection between earnings growth and upwards migration. Motivated by the model in Section 2, we use these estimates to show that earnings growth is a quantitatively important driver of migration.

6.1 Descriptive Evidence

Figure 3 shows how neighborhood choices vary with long-term earnings changes. In Panel A, we bin individuals by their change in real annual earnings over an eight-year horizon along the x-axis and plot the average difference in median income between their ending and baseline census tracts on the y-axis. Because the difference in tract median income is equal to 0 for individuals who do

[23] The most closely related result from Quillian (2003) is that, counting neighborhood change as an exit, 39.8 percent of individuals in a tract with over 20 percent poverty at time t are in a similarly high-poverty tract for all of the subsequent ten years. (We construct this estimate by pooling Quillian's estimates for White and Black individuals.) If we handle neighborhood change in the same way, the analogous estimate in our sample is 41.1 percent. In addition, Quillian (2003) finds very similar reductions in tract poverty among people exiting high-poverty areas (about 20 percentage points).

[24] Quillian (2003) finds that 46 percent of Black individuals in a poor tract at baseline live in a poor neighborhood for all of the following ten years, versus only 26 percent of White individuals (counting neighborhood change as an exit). The analogous estimates in our analysis are 44 percent and 36 percent, and the Black-White difference in mean years of exposure is only 0.5. These differences could emerge because Quillian studies the 1979 to 1990 period and defines concentrated poverty using a 20 percent threshold. Alternatively, they could result from sampling noise in the PSID, which contains fewer than 1,000 White individuals in poor neighborhoods: our estimate of the White "stayer" share is within the confidence interval of Quillian's.

not move, the average difference in each bin reflects both the frequency and direction of migration. We stratify individuals based on their baseline tract poverty rate, and we separate individuals who are nonemployed in both years from others.[25]

People with larger increases in earnings systematically move to higher-income tracts, and this relationship is strongest among those who begin in higher-poverty areas. Among individuals starting in the highest-poverty category, a $20,000–$30,000 increase in annual earnings is associated with a $4,700 larger gain in tract income than an earnings increase of $0–$10,000. In contrast, among individuals beginning in the lowest-poverty neighborhoods, the same difference in earnings growth is associated with only a $600 gain in tract income. The y-axis intercepts vary significantly across neighborhoods as well. The average employed person with no earnings change who began in the highest poverty category improves their tract income by $11,000, while those in the lowest-poverty tracts see a slight decrease in tract income. This points to differences in individuals' trajectories that are unrelated to earnings, potentially driven by life-cycle factors or mean reversion. Individuals who are nonemployed in both years see neighborhood improvement very similar to employed individuals with little change in earnings.

Changes in individual earnings are also associated with exit and entry into high-poverty neighborhoods. Panel B of Figure 3 considers individuals originating in high-poverty neighborhoods and plots the probability that they move to a lower-poverty category. For individuals with no earnings growth, the probability of exit is about 43 percent. This probability increases rapidly as earnings grow, with 54 percent of individuals with earnings growth of $20,000 to $30,000 exiting high-poverty neighborhoods.[26] As a comparison point, Panel C of Figure 3 focuses on individuals originating outside high-poverty neighborhoods and plots the probability that they live in one eight years later. People with lower earnings growth are more likely to enter a high-poverty neighborhood, especially those starting in a medium-poverty tract. This relationship is strongest for people with low baseline earnings (Appendix Figure A.4).

[25]Results are similar when stratifying individuals by baseline tract income quintile (Appendix Figure A.3).

[26]Using Canadian administrative data, Frenette et al. (2004) find that less than half of migration into or out of concentrated poverty coincides with a large earnings change or change in household composition.

6.2 Quasi-Experimental Methodology

While suggestive, these correlations need not reflect a *causal* effect of earnings growth on residential mobility. They may instead capture correlated life-cycle trends in both earnings and neighborhood choice. To isolate a causal effect, we exploit idiosyncratic shocks to pay at specific employers as in Koustas (2018) and Ganong et al. (2020). This type of unanticipated earnings change is particularly interesting to study in this context, as forward-looking individuals might make migration choices based on expected earnings in the future. The extent to which positive earnings shocks lead to neighborhood upgrading informs the degree to which affordability is a binding constraint in neighborhood choice, and it also has implications for place-based policy.

Our research design seeks to compare observationally similar individuals who are employed at observationally similar firms at baseline, but whose firms' payroll grows at different rates. Using idiosyncratic changes in pay at particular firms allows us to hold broader changes in neighborhood conditions constant. Following Rose and Shem-Tov (2023), we focus on individuals in our earnings sample who report working more than 1042 hours in the ACS, corresponding to approximately half-time employment.[27] We further restrict the sample to individuals for whom we can identify at least 25 coworkers in the LEHD data. Column 3 of Appendix Table A.1 presents summary statistics for this sample, which, by construction, contains individuals who are more likely to be consistently employed and have higher total income than individuals in the broader samples.

For each individual, we construct the "pay shock" as the average percent change in earnings among a holdout sample consisting of their coworkers who are observed in the LEHD but not sampled in the ACS between 2005 and 2013. We measure this earnings change between the baseline quarter (when the index individual was sampled in the ACS) and four quarters later.[28] Using year-over-year changes in earnings limits the impact of seasonality, and our restriction to individuals

[27] To limit the role of outliers, we treat person-years in which an individual earned less than $4,000 or over $300,000 in the LEHD as missing. Similar sample restrictions are common in the literature (e.g. Abowd et al. 2018).

[28] To better measure changes in firm payroll, we restrict the set of coworkers to those who earn more than $2,600 at baseline (roughly half-time employment at minimum wage) and are employed at the same firm from the quarter before baseline until the fifth quarter after baseline. To limit the influence of outliers, we successively winsorize individual earnings, the percent change in individual earnings, and the pay shock at the 99th percentile.

with at least 25 LEHD coworkers limits the noise in the pay shock variable.

To compare observably similar individuals at similar firms, we include both individual-level and firm-level controls in our primary specification, again following Rose and Shem-Tov (2023). The individual controls include: initial hourly wage (constructed using the ACS), 2005–2009 median income of the tract of residence in the ACS, age, sex, race, ethnicity, and education. Firm-level controls (computed using the holdout sample over the four quarters prior to the baseline) include: log firm employment, mean pay, median pay, average separation rate, average new worker accession rate, and average separation rate into non-employment.[29] Finally, we also include fixed effects that control for differential trends across industries and local labor markets. After the main results, we show robustness to specifications using a reduced set of controls and fixed effects.

The resulting regression specification for individual i sampled in year $a(i)$ is:

$$Y_{i,t} = \mu_i + \sum_{k \in \mathcal{E}} \beta_k \text{PayShock}_i \times \mathbb{1}[t = a(i) + k] + \theta_{t,q(i)} + \omega_{t,a(i),n(i),s(i)} + \lambda_{t,a(i),c(i)} + \sum_{k \in \mathcal{E}} X_i' \alpha_{a(i),k} \times \mathbb{1}[t = a(i) + k] + \epsilon_{i,t}, \tag{7}$$

where $Y_{i,t}$ is the outcome of interest in year t, $\mathcal{E}$ is the set of years used to estimate the event-study coefficients (-5 to 8, excluding -1), and $q(i)$ references the specific quarter-year the individual was sampled. We scale the PayShock_i variable so that coefficients can be interpreted as the effects of a 10 percent year-over-year increase in coworker earnings, which is slightly more than one standard deviation of the shock.[30] We control for common trends among individuals sampled in the same quarter-year using the fixed effects $\theta_{t,q(i)}$. The fixed effects $\omega_{t,a(i),n(i),s(i)}$ allow trends in outcomes to vary arbitrarily based on individuals' sampling year ($a(i)$), baseline 2-digit NAICS industry ($n(i)$), and baseline state of residence ($s(i)$). The fixed effects $\lambda_{t,a(i),c(i)}$ additionally absorb variation in changes over time by sampling year and baseline CBSA of residence ($c(i)$). X_i is the vector of individual and firm-level controls, which are interacted with relative time dummies

[29] To allow for flexible functional forms, we use indicator variables for quintiles of control variables that are continuous (including hourly wage, 2005–2009 median income of the tract of residence in the ACS, age, log firm employment, mean pay, median pay, separation rate, new worker accession rate, and separations into non-employment).

[30] The mean of the pay shock is 2.2 percent and the standard deviation is 9.1 percent.

and allowed to vary across ACS sample cohorts.

6.3 Causal Effects of Earnings Changes on Migration

Panel A of Figure 4 shows the dynamic effects of coworker pay shocks on several labor market outcomes. A 10 percent increase in coworker earnings is associated with an immediate increase in individual annual earnings of about 2.5 percent.[31] There is little evidence of a change in earnings in previous years, consistent with limited anticipation of these changes. Although the shocks are defined using coworker earnings changes in a single year, the effect is persistent and reverts only gradually, remaining elevated by 1 percent in year 8. *Cumulative* earnings effects thus grow over time. The effect on household earnings (defined using partners reported in the ACS) is slightly smaller, reflecting the presence of multiple earners in many households.

Figure 4 also shows the effect of a pay shock on separations. We find that a positive shock increases the probability of remaining at one's initial firm, which, all else equal, might lower the incentive to migrate. Analogously, a negative shock should have the opposite effect.

Turning to the effects on migration, Panel B of Figure 4 shows that individuals with more positive pay shocks are more likely to move, with a cumulative effect size reaching 0.4 percentage points eight years after the initial shock. Our earlier results indicate that the baseline probability of moving over an eight-year period is roughly 40 percent, implying a 1 percent increase in the probability of moving in response to a persistent 1–2 percent increase in annual earnings. Interestingly, this increase is accounted for almost entirely by induced moves to higher-income tracts.

Figure 5 considers the relationship between the coworker pay shock and tract median household income and home value.[32] More positive shocks generate moves towards tracts with higher quality. In contrast to the effects on earnings, which fade over time, the effects on neighborhood quality *increase* over time, reaching roughly 0.25 percent at their peak. One potential explanation

[31] Our first-period estimate of 2.5 percent is smaller than Koustas (2018) (4.1 percent) and Ganong et al. (2020) (3.8 percent). This may occur because we measure annual earnings, while they use bimonthly or monthly earnings.

[32] We use these measures of neighborhood quality because poverty rates are relatively flat in the upper third of the quality distribution, which blunts estimates based on samples that include individuals living in all types of neighborhoods at baseline. Appendix Figure A.5 shows that positive pay shocks also lead to moves to tracts with a lower poverty rate.

is that moving costs make long-run income expectations, rather than current income, the primary driver of relocation decisions. Mobility then rises as workers learn whether a shock is permanent. Relocation decisions may also be sensitive to accumulated earnings changes, particularly for credit-constrained individuals buying homes.[33]

To assess the magnitude of these effects, it is helpful to benchmark the long-term effect on neighborhood quality to the effect on household earnings. We estimate a variant of equation (7) that pools periods into a pre-shock period, a short-run post period ($k \in [1, 3]$), and a long-run post period ($k \in [4, 8]$). We report estimates of this long-run post period coefficient in the first row of Table 5. Taking the ratio of the effect on log tract income (0.0018) to the effect on log own household earnings (0.0127) yields an elasticity of 0.140. Put differently, a coworker pay shock that increases long-run earnings by 10 percent also leads individuals to move to a neighborhood that has 1.4 percent higher median income. While individuals do not perfectly sort to a neighborhood that matches their new income after a shock, they do systematically move to better neighborhoods. The elasticity implies that a log earnings increase equal to the population average of 0.08 should result in a move to a tract with 0.011 higher log income, which is 35 percent of the actual average change of 0.032.[34]

6.4 Heterogeneity Across Subgroups

Table 5 describes heterogeneity across key subgroups in these estimates. It also includes the average earnings growth and average neighborhood improvement for each subgroup, which we use to decompose migration towards better neighborhoods into factors related to earnings versus other

[33]Our preferred regression specification includes many controls, but our results are also robust to alternative approaches. Appendix Figure A.6 replicates Figure 5 using only controls for industry, initial wage, initial tract income, and age; this specification excludes state fixed effects, CBSA fixed effects, and firm-level controls and fixed effects. The results from the two specifications are nearly identical.

[34]In related work, Hilger (2016) estimates the impact of a layoff on zip code median house value using a sample of fathers observed in tax data. The implied elasticity of zip code median house value to earnings is 0.07 (reflecting a 1.2 percent decrease in zip code median house value and a 17.7 percent decrease in earnings five years after layoff). Our approach differs in the sample composition, use of a range of coworker pay shocks (not layoffs) that include intensive-margin earnings changes, and focus on tracts instead of zip codes. In contrast, studies of transitory windfalls like winning the lottery (Golosov et al., 2023) and temporary receipt of an unconditional cash transfer (Bartik et al., 2024) find positive effects on migration from baseline residence but no evidence of relocation to higher-income neighborhoods. This difference may occur because these shocks are not persistent.

factors.

Estimated elasticities of tract income to own income vary widely, with the most striking contrasts appearing between renters and homeowners (0.262 vs. 0.072), and between individuals with and without children (0.204 vs. 0.092). We also find a substantially lower elasticity for White individuals than others. The elasticity differences are driven primarily by differences in the estimated effects of the shocks on neighborhood income, rather than differences in the effects on household earnings.

The model in Section 2 provides three explanations for these cross-group differences. First, the complementarity channel predicts higher elasticities for groups whose valuation of neighborhood quality rises more steeply in income. This is a natural explanation for why the elasticity of individuals with children exceeds that of individuals without children. This channel also depends on the variance of quality across neighborhoods, which may explain why the elasticity is greater in larger metro areas. Second, the budget-constraint channel predicts higher elasticities for lower-income groups, which could explain why the elasticity is larger for people in higher-poverty neighborhoods. Finally, we expect higher elasticities for groups with smaller idiosyncratic attachments or lower moving costs. This could explain why renters are more responsive than homeowners.

The results in Table 5 allow us to empirically decompose mobility towards better neighborhoods into a component explained by earnings increases—given by the product of average earnings growth and the elasticity of neighborhood quality to earnings—and a non-earnings component (with the caveat that this requires applying an elasticity identified from firm-driven earnings shocks to a broader set of earnings changes). The two components, shown in columns 7 and 8, both matter, with notable heterogeneity across groups. For renters, earnings growth explains 64 percent of the observed gain in neighborhood income, reflecting both a large elasticity and sizable earnings growth. By contrast, it explains only 18 percent among homeowners, who have a lower elasticity and experience smaller household earnings growth.

Finally, the results highlight several distinct explanations for disparities in mobility towards better neighborhoods across groups. In some cases, disparities can arise due to differences in

responsiveness to income changes (i.e., elasticities), in other cases due to differences in average earnings growth, and in yet others due to differences in the non-earnings component. We find that younger individuals are more likely to move to better neighborhoods than older individuals despite similar elasticities—in this case, the larger earnings growth among the young drives the difference. By contrast, we find that Hispanic individuals experience larger neighborhood improvements than White individuals despite nearly identical earnings growth because they have a much larger elasticity. There are also cases where mobility differs substantially across groups *despite* similar earnings growth and similar elasticities. In particular, individuals in neighborhoods with poverty rates of 10–20 percent are much more likely to move to better neighborhoods than individuals in the lowest poverty neighborhoods despite similar elasticities and earnings growth rates, suggesting some degree of convergence towards better neighborhoods that occurs irrespective of earnings growth.

6.5 Estimates in High-Poverty Neighborhoods

Finally, we consider high-poverty neighborhoods. Due to the relatively small share of people who live in neighborhoods where the poverty rate exceeds 30 percent, we decrease the high-poverty threshold to 20 percent and use continuous neighborhood quality measures as outcomes (rather than exit from concentrated poverty as in some of our descriptive analyses). The last row of Table 5 reports estimates for individuals living in poor tracts at baseline, and Appendix Table A.7 breaks them out by housing tenure and the presence of children. Individuals in poor neighborhoods are especially responsive to earnings increases: the implied elasticity of 0.29 is the highest of any subgroup. Applied to their earnings growth of 0.079 (near the sample average), this yields a predicted 2.3 percent improvement in tract income, again among the highest of any subgroup. This suggests that affordability is indeed a binding constraint for many people in poor neighborhoods. Renters and those with children upgrade neighborhoods the most in response to positive earnings shocks, consistent with our analysis of longitudinal exposure in Table 4.

However, although this earnings component is large relative to other groups, it is only a small share of the average neighborhood improvement of 23 percent experienced by high-poverty res-

idents. Most movement out of poor neighborhoods appears to be driven by factors other than earnings growth. In the context of our model, this points to a significant role for changes in earnings and an even larger one for changes in match-specific preferences and constraints.

7 Implications for Poor Neighborhoods and Place-Based Policy

7.1 Estimating the Pass-Through of Individual Earnings Growth to Neighborhoods

Our individual-level results have shown the existence of each element of Jacobs's account of concentrated poverty. We now use the pass-through concept from Section 2.2 to bring these estimates together and quantify the importance of this mechanism for the persistence of concentrated poverty. We compare the earnings growth among the *initial* cohort of residents in high-poverty neighborhoods ($\bar{y}_t^{\text{cohort}}$) to the earnings of the same neighborhoods' *contemporaneous* residents in subsequent years ($\bar{y}_t^{\text{place}}$). The ratio of the two provides the pass-through measure ρ_t in equation (5). Intuitively, the initial cohort's earnings growth reveals how much individual economic improvement a neighborhood could conceivably capture, and the pass-through rate summarizes how much growth in fact remains in the neighborhood.

We first compute $\bar{y}_t^{\text{cohort}}$ for each tract poverty category, using responses in the 2005 to 2009 ACS waves to form a baseline. We restrict to the 1965 to 1980 birth cohorts to minimize the roles of retirement and sample entry. As shown in Figure 6, the initial cohort's earnings growth is large over the subsequent ten years for every category, between 24 and 26 percent in real terms. This is consistent with our results on individual earnings growth.

We next compute $\bar{y}_t^{\text{place}}$ for each tract type (restricting to the same birth cohorts). In low-poverty tracts, neighborhood average earnings grow at about the same rate as the earnings of individuals who began in those neighborhoods. However, this is not true in either the 20–30 or 30+ percent poverty neighborhoods, where contemporaneous resident earnings grow by only 11 percent over the ten-year period, even though earnings of their initial residents grow by about 25 percent. In levels, the average earnings of poor neighborhoods' initial cohort increase by $5,300, while earnings

of their contemporaneous residents increase by only $2,300. The resulting pass-through rate for high-poverty neighborhoods is 0.427, and the 0–10, 10–20, and 20–30 percent poverty categories see pass-through of 0.940, 0.625, and 0.473.[35]

We can decompose the low pass-through rate in poor neighborhoods using equation (5):

$$\rho_{10} = 1 - \frac{\pi_{10}^{\text{exit}}\left(\bar{y}_{10}^{\text{exit}} - \bar{y}_{10}^{\text{stay}}\right) + \pi_{10}^{\text{entr}}\left(\bar{y}_{10}^{\text{stay}} - \bar{y}_{10}^{\text{entr}}\right)}{\bar{y}_{10}^{\text{cohort}} - \bar{y}_{0}^{\text{cohort}}} = 1 - \frac{0.56(6,900) + 0.29(-2,900)}{5,300}. \quad (8)$$

The first term in the numerator shows the importance of selective out-migration. The exiter group has earnings $6,900 above the stayer group in year 10, and 56 percent of baseline residents live outside of the set of poor neighborhoods in year 10. The second term shows that entrants—who account for 29 percent of residents in year 10—have earnings $2,900 above stayers, which partially offsets the out-migration of higher earners. We plot the percentage contribution of these two channels to overall pass-through in Figure 7. The exit channel reduces the pass-through of the initial cohort's earnings growth by 73 percent, while the entrant channel offsets this by 16 percent, resulting in the ultimate 0.427 estimate ($= 1 - 0.73 + 0.16$).

Appendix Figure A.7 further plots the evolution of earnings for stayers, exiters, and entrants in poor neighborhoods in each year. One notable takeaway is that average earnings among entrants grows at a similar rate over time as that of exiters, but from a lower level. This is consistent with many of the entrants being at an earlier point in the same kind of residency spell that the exiters have just completed.

These results suggest that the migration mechanism proposed by Jacobs is a quantitatively important driver of concentrated poverty's persistence. Various macroeconomic fluctuations and local economic shocks may affect individual outcomes, but selective migration in poor areas limits their pass-through to neighborhood-level outcomes. This is a sharp contrast to a pure poverty trap story in which poor neighborhoods persist due to depressed earnings growth and low migration rates. It is also quite different from low-poverty neighborhoods, where the exact opposite dynamics

[35]The pass-through rates need not average to one because the population in each neighborhood category changes over time. For example, relatively high-earners in poor neighborhoods may move to rich neighborhoods in which they are relatively low-earners, reducing average earnings in both places.

play out: stayers are positively selected, and entrants have higher earnings than exiters (Appendix Figure A.7).

7.2 Implications for Place-Based Policy

Our results have important implications for a broad set of policies that seek to connect residents of poor neighborhoods to better job opportunities. Examples include the provision of employment assistance to public-housing residents through the Jobs Plus program, community hiring provisions that aim to tie government procurement to the employment of residents of poor neighborhoods, and the large number of enterprise zone programs. There are two key reasons why these types of programs might benefit targeted neighborhoods by less than their initial residents. First, the high baseline migration rates out of poor neighborhoods may lead much of the gains created by these programs to leak out of the neighborhood. Second, this dynamic could be exacerbated if program-induced increases in individuals' economic standing lead them to move elsewhere.

Our estimates allow us to do some back-of-the-envelope calculations on the likely size of these two channels. As an example, we calculate the expected pass-through of a hypothetical program that targets people in high-poverty neighborhoods and has the same effect on earnings as Project QUEST, a successful sectoral employment program that helps participants find and prepare for healthcare jobs in San Antonio. In a randomized controlled trial of Project QUEST from 2006–2015, participants had baseline earnings of $11,722, which grew to $27,363 after eight years for the control group and $30,315 for the treatment group (Roder and Elliott, 2021).[36]

If we enrolled one person in this program, how would expected earnings in their neighborhood change? This requires a comparison between place and cohort earnings across *treatment statuses*, whereas our earlier pass-through estimates considered differences *over time*. To reflect this difference, we define:

$$\rho_t^{\text{policy}} \equiv \frac{\bar{y}_t^{\text{place},1} - \bar{y}_t^{\text{place},0}}{\bar{y}_t^{\text{cohort},1} - \bar{y}_t^{\text{cohort},0}}, \tag{9}$$

[36] Similar sectoral employment programs have successfully boosted participant earnings in a number of randomized controlled trials (Katz et al., 2022).

where, for example, $\bar{y}_t^{\text{place},D}$ is expected average earnings in the neighborhood given the target individual's treatment status $D \in \{0, 1\}$. We calculate ρ_t^{policy} using different estimates of the causal effect of earnings changes on migration and under different assumptions about heterogeneity in the employment program's earnings effects. Results are shown in Table 6. Throughout, we assume that if the target individual exits, their housing unit is filled by an entrant whose earnings do not vary with the targeted individual's treatment status. In addition, we assume that untargeted individuals have the same outcomes in either state of the world.

First, suppose that the treatment effect is uniform. Equation (9) can be written as:

$$\rho_t^{\text{policy}} = \frac{(1 - \pi_t^{\text{exit},1})y_t^1 + \pi_t^{\text{exit},1}\bar{y}_t^{\text{entr}} - (1 - \pi_t^{\text{exit},0})y_t^0 - \pi_t^{\text{exit},0}\bar{y}_t^{\text{entr}}}{y_t^1 - y_t^0}, \tag{10}$$

where $\pi_t^{\text{exit},D}$ is the probability that the targeted individual exits by time t given treatment status D, y_t^D is the earnings of the targeted individual, and $\bar{y}_t^{\text{entr}}$ is average entrant earnings. Nearly all of these quantities can be drawn directly from either our earlier estimates or Roder and Elliott (2021).[37] However, $\pi_t^{\text{exit},1}$ depends on the causal effect of the earnings increase on the exit rate and is more difficult to estimate. Our causal estimates from Section 6 point to a value of 0.534, which yields an overall estimate of $\rho_t^{\text{policy}} = 0.439$.[38] If we instead assume that the program-induced increase in earnings has no effect on migration ($\pi_t^{\text{exit},0} = \pi_t^{\text{exit},1}$), the estimate is 0.483. The small difference between these estimates suggests that high baseline exit rates are the dominant source of limited pass-through in this scenario, as program-induced exits are relatively uncommon.

Second, suppose that the policy has more concentrated earnings effects, with the average effect of $2,952 resulting from a 10 percent probability of a $29,520 increase and a 90 percent probability

[37]The Project QUEST results provide y_t^D, and we set average entrant earnings $\bar{y}_t^{\text{entr}}$ equal to $23,000 based on Appendix Table A.6. We draw an exit rate in the untreated state $\pi_t^{\text{exit},0}$ of 0.517 by evaluating the graph in Panel B of Figure 3 at the control group's earnings change.

[38]Recall that due to sample size constraints, our coworker shock estimates for high-poverty neighborhoods use a 20 percent poverty threshold to define the sample and continuous measures of neighborhood quality as outcomes. To translate these estimates to the effect on exit from tracts over 30 percent poverty, we first take the ratio of the OLS relationship between earnings changes and tract income in Figure 3, Panel A to the implied causal elasticity between the same quantities from Section 6.2. We then apply this ratio to the OLS estimate of the relationship between earnings changes and high-poverty exit in Figure 3, Panel B.

of no change.[39] In this case, the pass-through rate falls substantially to 0.279. This occurs because the estimated probability of exit rises from 0.534 to 0.694 in the case of the large earnings increase, illustrating that program-induced exits may be more important when some individuals see very large earnings gains and become much more likely to exit concentrated poverty.

While these estimates rely on simple back-of-the-envelope calculations, results from the Jobs Plus program, which targeted individuals living in a set of public housing developments, suggest that similar mechanisms play out in reality. The program produced significant income improvements for individuals but had little effect on the targeted public housing complexes as a whole (Miller et al., 2023).

Finally, our results suggest a path to neighborhood revitalization that sidesteps common concerns about gentrification. Jacobs (1961) argued that high-poverty neighborhoods can be improved without large-scale residential turnover by "creating conditions aimed at persuading residents to stay by choice over time." Our results suggest that earnings growth in poor neighborhoods is strong enough that increasing retention of people whose income increases would meaningfully boost average neighborhood income. For example, returning to Figure 6, if poor neighborhoods had the same pass-through as neighborhoods with 10–20 percent poverty (0.625 instead of 0.427), their mean earnings would have grown by 44 percent more ($3,300 rather than the observed $2,300). Policies that improve neighborhood amenities may operate through this channel: current residents at the margin of moving away likely respond to amenity improvements more strongly than potential newcomers, since they can benefit without paying moving costs. While this alleviates some worries about involuntary displacement or cultural change, improving a neighborhood may still raise housing prices and create affordability challenges for lower-income residents.

[39] We calculate pass-through in this case by replacing the first two terms in the numerator of equation (10) with $0.1((1-\pi_t^{\text{exit,big}})y_t^{\text{big}} + \pi_t^{\text{exit,big}}\bar{y}_t^{\text{entr}}) + 0.9((1-\pi_t^{\text{exit,0}})y_t^{0} + \pi_t^{\text{exit,0}}\bar{y}_t^{\text{entr}})$, where $\pi_t^{\text{exit,big}}$ is the probability of exit given the large earnings increase and y_t^{big} is the associated earnings level.

8 Conclusion

This paper uses newly available administrative data linking survey responses, longitudinal address histories, and employer-employee earnings records to characterize the joint dynamics of migration and earnings in poor neighborhoods. In our individual-level analysis, three facts stand out. First, earnings growth among residents of high-poverty neighborhoods closely resembles that of residents elsewhere, including a substantial right tail of large gains. Second, residential mobility out of high-poverty neighborhoods is high, with half of residents leaving within a decade, and the large majority of movers relocating to lower-poverty areas. Last, increases in earnings shift households toward higher-income neighborhoods, with an elasticity of neighborhood income to own earnings that is largest for renters and families with children.

Why do these individual dynamics matter? They explain a good deal about why concentrated poverty persists. A sizable upwardly mobile group breaks the link between changes in individual and neighborhood income, so a place can remain poor even as many people who pass through it do not. This has direct implications for policy. Programs that successfully raise the earnings of residents in targeted neighborhoods may show little neighborhood-level effect, because high baseline mobility—amplified by the very income gains the programs generate—causes benefits to leak out of the target area. Conversely, policies that increase retention of upwardly mobile residents, for instance by improving local amenities, could meaningfully raise average neighborhood income.

Our results also raise welfare questions that merit further study: if some households deliberately use inexpensive, high-poverty neighborhoods to smooth consumption or economize while young—as Kennan and Walker (2011) and Bilal and Rossi-Hansberg (2021) show at broader geographic levels—eliminating such neighborhoods could impose meaningful costs. Quantifying these trade-offs in dynamic models with realistic earnings risk is a natural direction for future work. As longitudinal individual data become more widely available, researchers could also extend our analysis to other settings. Slums in developing countries would be a particularly interesting, albeit challenging, setting (Marx et al., 2013).

Figure 1: Distribution of Eight-Year Earnings Changes, By Baseline Tract Poverty Rate

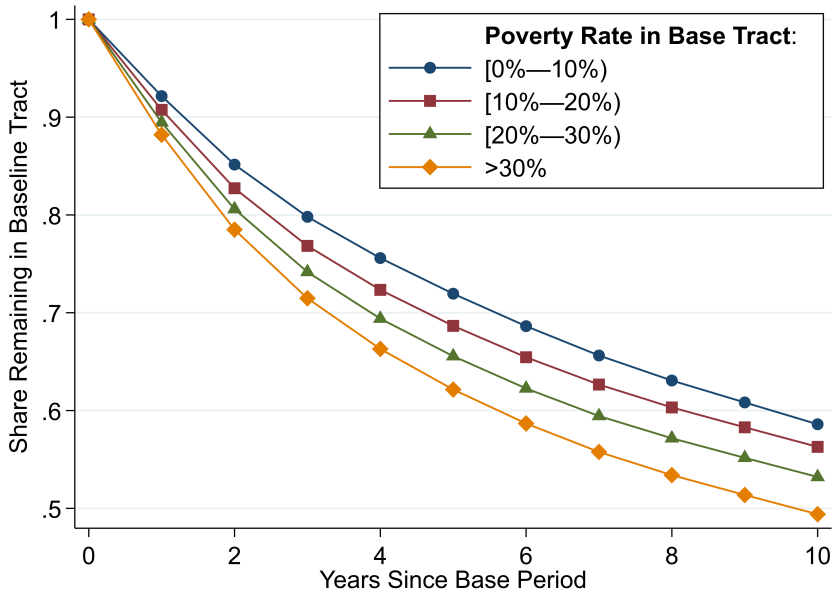

Notes: This figure shows the distribution of earnings changes over an eight-year period that starts when an individual is sampled in the ACS. Individuals are stratified based on their baseline tract's poverty rate. The left- and right-most bins are open-ended. If an individual has no earnings reported in the start or end year, earnings are treated as zero for that year. If earnings are missing or below $4,000 in both the start and end year, individuals are binned separately in the "Nonemployed" category. The percent that is in the Nonemployed category is displayed in the top-right corner in each histogram. The figure uses the earnings sample, as described in Section 3.2.

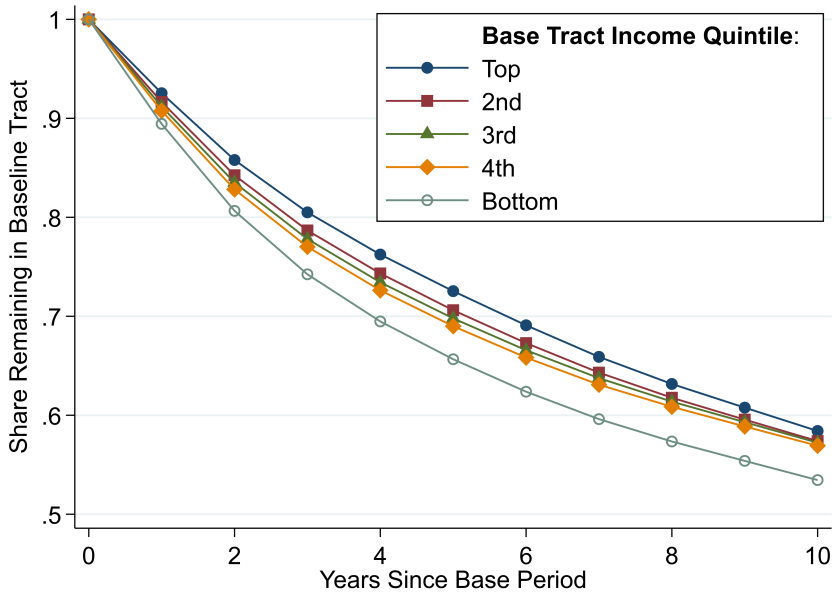

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

Figure 2: Share of Individuals Remaining in Baseline Tract Over 10 Years

(a) By Baseline Tract Poverty Rate Category

(b) By Baseline Tract Income Quintile

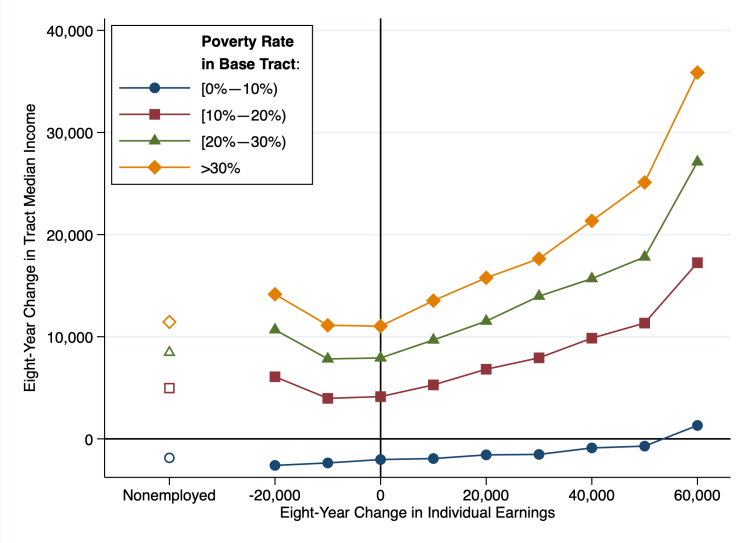

Notes: This figure shows the share of individuals who live in their baseline census tract for each of the 10 years after the baseline year (the year an individual is sampled in the ACS). Individuals are stratified based on the baseline tract's poverty rate (Panel A) or quintile of median household income (Panel B). This figure uses the migration sample, as described in Section 3.2.

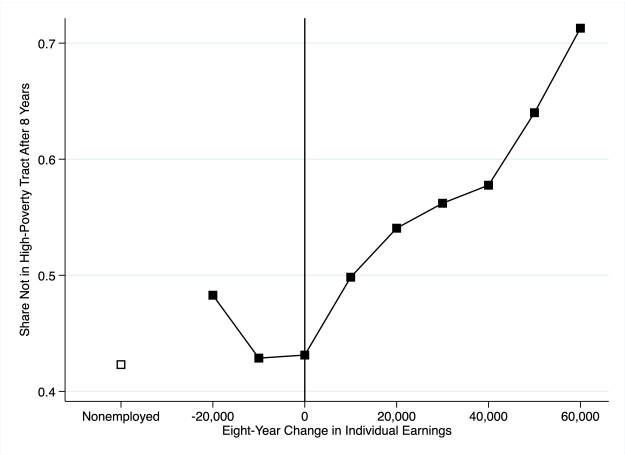

Source: Authors' calculations using data from the ACS and MAFARF.

Figure 3: Tract Mobility and Earnings Growth Over Eight Years

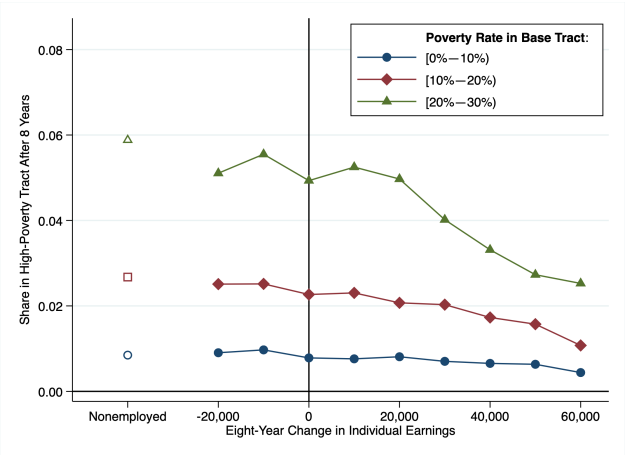

(a) Movement to Higher-Income Tracts, by Baseline Tract Poverty

(b) Exit From High-Poverty Tracts

(c) Entry Into High-Poverty Tracts

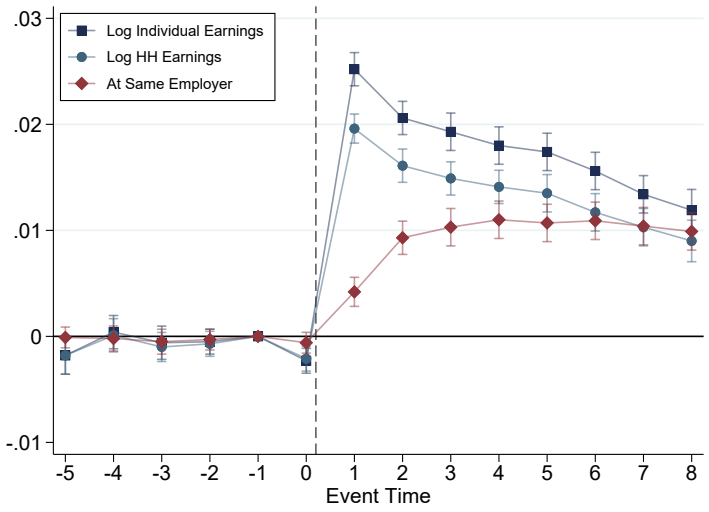

Notes: Figure presents binned scatter plots that show the average change in tract characteristics between each individual's baseline tract and the tract they live in eight years later for different levels of earnings changes over an eight-year period that starts when an individual is sampled in the ACS. If an individual has no earnings reported in the start or end year, earnings are treated as zero for that year. If earnings are missing or below $4,000 in both the start and end year, individuals are binned separately in the "Nonemployed" category. The y-axis variable in Panel A is the average difference in tract median household income between the individual's baseline tract and the tract they live in eight years later in each earnings change bin, where individuals are further stratified based on the poverty rate of their baseline tract. Panel B shows the average probability of transitioning out of a high-poverty tract (baseline poverty rate over 30 percent) for those beginning in a high-poverty tract. Panel C shows the average probability of transitioning into a high-poverty tract for those who do not begin in a high-poverty tract, with individuals further stratified based on the poverty rate of their baseline tract. The left- and right-most bins are open-ended. The figure uses the earnings sample, as described in Section 3.2.

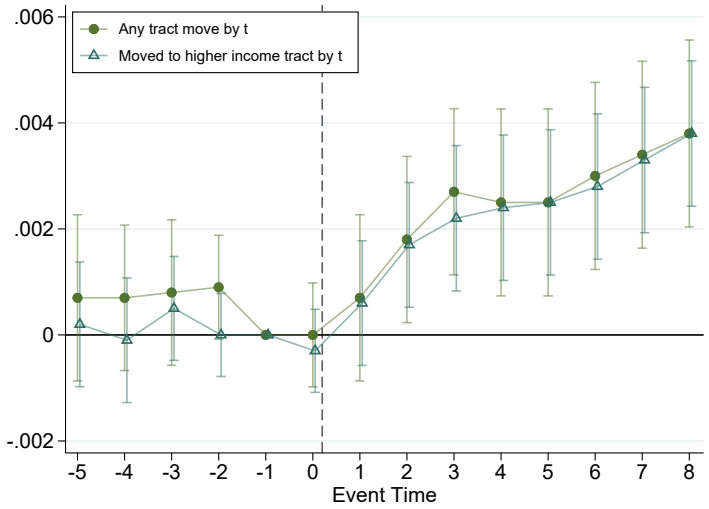

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

Figure 4: Effects of a Coworker Earnings Shock on Labor Market and Migration Outcomes

(a) Effects on Labor Market Outcomes

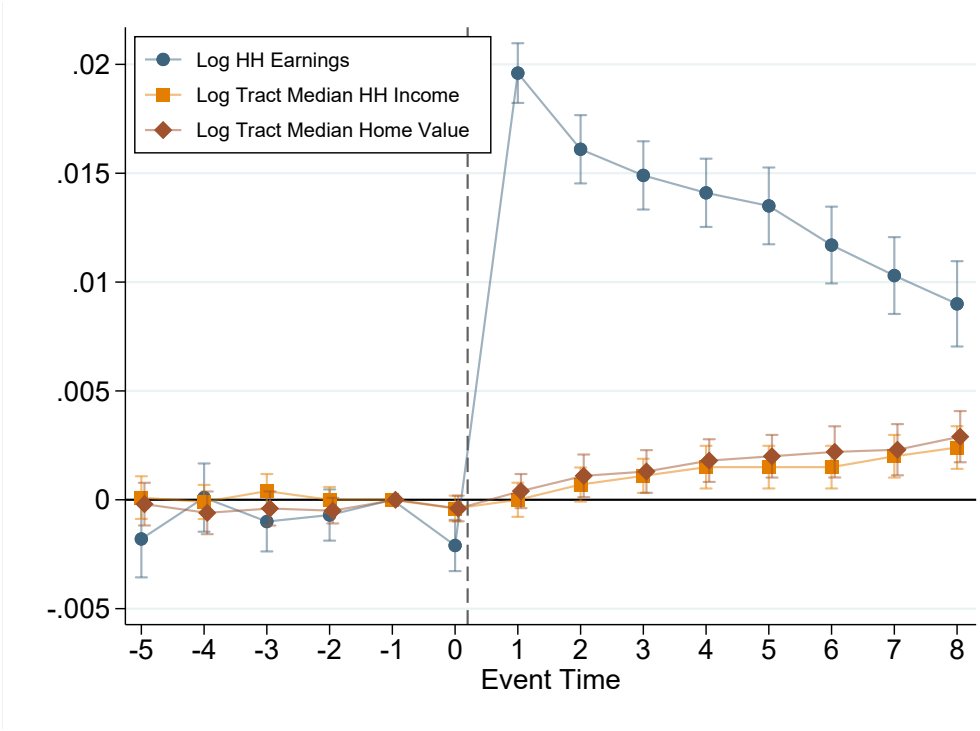

(b) Effects on Migration Outcomes

Notes: This figure displays OLS estimates of equation (7) with 95 percent confidence intervals. The figure uses a subset of the earnings sample consisting of individuals working at firms with at least 25 employees in the holdout sample, as described in Section 6.2. Effects are scaled so that coefficients can be interpreted as the effect of a 10 percent increase in coworker quarterly earnings over a four-quarter period that begins when an individual is sampled in the ACS. Panel A displays effects on the log of individual LEHD annual earnings, the log of household LEHD earnings (defined as the sum of one's own earnings and the earnings of any other individual who was a spouse or partner in the base year in the ACS), and an indicator for remaining at the baseline firm. Panel B displays effects on the cumulative probability of having moved from one's baseline tract and the cumulative probability of moving to a tract with a higher median household income than one's baseline tract. Standard errors are clustered at the firm level, and ACS sampling weights are applied.

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

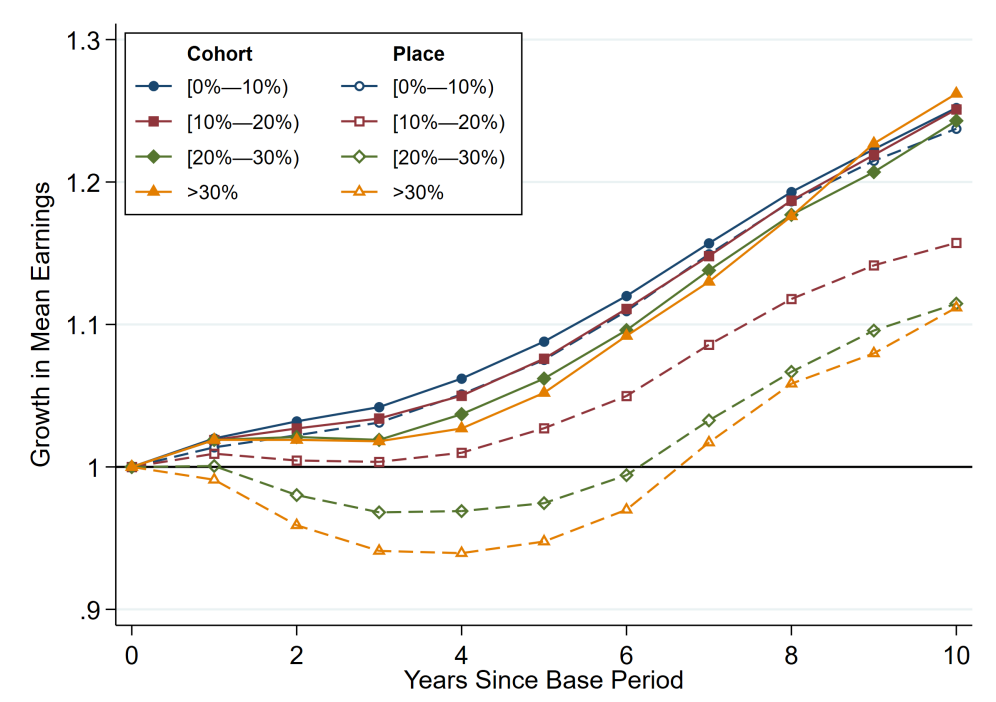

Figure 5: Effects of a Coworker Earnings Shock on Neighborhood Choice

Notes: This figure displays OLS estimates of equation (7) with 95 percent confidence intervals. The figure uses a subset of the earnings sample consisting of individuals working at firms with at least 25 employees in the holdout sample, as described in Section 6.2. Effects are scaled so that coefficients can be interpreted as the effect of a 10 percent increase in coworker quarterly earnings over a four-quarter period that begins when an individual is sampled in the ACS. The outcomes are the log of household LEHD earnings (reproduced from Panel A of Figure 4 for comparison), along with the log median household income and log median house value (calculated from 2005–2009) of the tract where individuals reside in each year. Standard errors are clustered at the firm level, and ACS sampling weights are applied.

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

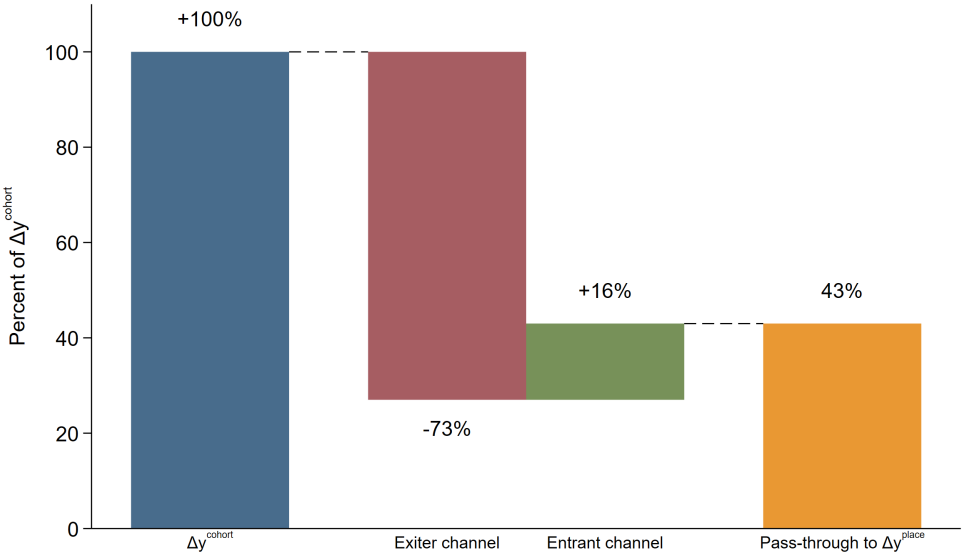

Figure 6: Cohort Earnings Growth Versus Place Earnings Growth

Notes: This figure compares the evolution of average earnings among the individuals residing in a neighborhood poverty category in each year ("place") and among the individuals who initially resided in each neighborhood category in the baseline year ("cohort"). Average earnings for initial resident cohorts appear in solid lines, and earnings for contemporaneous place residents are in dashed lines. The exercise uses the earnings sample, as described in Section 3.2, and further restricts to the 1965 to 1980 birth cohorts to minimize the role of retirement and sample entry. Mean earnings in each year are normalized by the poverty category's mean earnings in the baseline year. Initial resident cohorts beginning in 2005 to 2009 are included, and the contemporaneous resident lines represent the average of the relevant comparison years for each of the initial cohorts (e.g., year 1 is the average of 2006 to 2010 residents).

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

Figure 7: Pass-through of Individual Earnings Growth to Neighborhood Earnings Growth

Notes: This figure shows how the ten-year earnings growth of initial residents of high-poverty neighborhoods passes through to growth in the average earnings in these neighborhoods. Using equation (8), we decompose the pass-through into the portion driven by the exit channel and the entrant channel. Each bar is relative to the earnings growth from initial residents of high-poverty neighborhoods. The first bar plots the earnings growth from initial residents of high-poverty neighborhoods $(\bar{y}_{10}^{\text{cohort}} - \bar{y}_{0}^{\text{cohort}})/(\bar{y}_{10}^{\text{cohort}} - \bar{y}_{0}^{\text{cohort}}) = 1$. The second bar plots the portion of the pass-through driven by the exit channel, $\pi_{10}^{\text{exit}}\left(\bar{y}_{10}^{\text{exit}} - \bar{y}_{10}^{\text{stay}}\right)/(\bar{y}_{10}^{\text{cohort}} - \bar{y}_{0}^{\text{cohort}})$. The third bar plots the portion of the pass-through offset by the entrant channel, $\pi_{10}^{\text{entr}}\left(\bar{y}_{10}^{\text{stay}} - \bar{y}_{10}^{\text{entr}}\right)/(\bar{y}_{10}^{\text{cohort}} - \bar{y}_{0}^{\text{cohort}})$. The final bar plots ρ_{10}, the pass-through of household earnings growth to the neighborhood after 10 years.

Table 1: Labor Force Transition Frequency by Baseline Neighborhood Type

	(1) Nonemployed to employed	(2) Nonemployed to nonemployed	(3) Employed to nonemployed	(4) Employed to employed
Panel A: Tract poverty rate				
0–10	0.072	0.262	0.097	0.569
10–20	0.073	0.267	0.108	0.552
20–30	0.081	0.284	0.115	0.520
30+	0.092	0.306	0.120	0.482
Panel B: Quintile of tract income				
1	0.084	0.293	0.117	0.507
2	0.073	0.268	0.109	0.550
3	0.070	0.258	0.103	0.569
4	0.070	0.254	0.099	0.578
5	0.076	0.274	0.095	0.556

Notes: This table reports the share of individuals in different neighborhood types who made each type of labor force transition over the eight years following their ACS response. We define nonemployment as LEHD earnings below $4,000. Rows in Panel A correspond to the poverty rate of the individual's baseline census tract, classified using 2005–2009 ACS data. Rows in Panel B correspond to population-weighted quintiles of 2005–2009 tract median household income.

Notes: This table reports regressions in which the dependent variable is the change in individual earnings over the eight-year period that starts when an individual is sampled in the ACS, measured in dollars (Panel A) or the arc percent (Panel B). For people with zero earnings in both periods, the arc percent is set to zero. The key explanatory variables of interest are indicators for the poverty rate of the neighborhood where an individual is observed at the start of the eight-year period; the omitted indicator is for the poverty rate above 30 percent. Columns 2 and 3 include CBSA and year fixed effects. Column 3 includes fixed effects for individual race, ethnicity, age, and baseline education. Standard errors, clustered at the level of the baseline tract, are reported in parentheses.

Table 3: Eight-Year Transition Rates Across Neighborhood Types

Panel A: Neighborhood poverty rate

	Year $t+8$				
Year t	0–10	10–20	20–30	30+	Individuals
0–10	88.4	8.7	2.2	0.8	7,370,000
10–20	19.8	73.6	4.6	2.0	3,890,000
20–30	16.1	14.9	64.6	4.5	1,300,000
30+	12.7	13.9	9.8	63.5	672,000

Panel B: Quintile of tract median income

	Year $t+8$					
Year t	1	2	3	4	5	Individuals
1	71.8	10.4	8.2	6.1	3.5	2,070,000
2	7.8	70.3	9.2	7.7	5.0	2,610,000
3	5.1	7.5	70.6	9.5	7.3	2,780,000
4	3.2	5.3	7.8	72.5	11.2	2,820,000
5	1.8	3.1	5.2	9.1	80.9	2,950,000

Notes: This table reports the share of people who start in each type of neighborhood in year t (the year they are sampled in the ACS) that end up in each type of neighborhood in year $t+8$. We classify census tracts based on 2005–2009 poverty rates in Panel A and population-weighted quintiles of the 2005–2009 median household income distribution in Panel B. This exercise uses the migration sample, as described in Section 3.2. The last column reports the rounded number of individuals in the sample who start in each type of neighborhood.

Notes: This table provides summary statistics among individuals in the migration sample who are observed living in a high-poverty neighborhood (where the 2005–2009 poverty rate exceeds 30 percent) in the year they are sampled in the ACS. Column 1 reports the number of observations. Columns 2–4 report the share of individuals who spend less than or equal to 5, 6 to 9, or 10 of the subsequent 10 years in a high-poverty neighborhood. Column 5 reports the mean number of years (out of the following 10) that individuals spend in a high-poverty neighborhood. Column 6 reports the share of individuals who spend 10 years in a tract that initially has a poverty rate above 30 percent but falls below 25 percent in the 2015-2019 ACS. Individual characteristics are taken from ACS responses, except for public housing and voucher use, which are drawn from HUD data. The CBSA rent gap variable is equal to the log of the mean rent in high-poverty tracts minus the log of mean rent in tracts with poverty between 20 and 30 percent. We restrict to individuals who were observed in the MAFARF in at least 8 of the 10 years following their ACS year, proportionally adjusting exposure of those observed in fewer than 10 years.

Notes: This table reports heterogeneity in the effects of coworker earnings shocks on household earnings and neighborhood choice across demographic and neighborhood subgroups, together with a decomposition of mean neighborhood upgrading. Estimates are based on a variant of equation (7) that pools periods into a pre-shock period, a short-run post period ($k \in [1, 3]$) and a long-run post period ($k \in [4, 8]$); the table reports the $k \in [4, 8]$ coefficient throughout. Column 1 reports the pooled estimate of the coworker pay shock on log household LEHD earnings, with standard errors clustered at the firm level in column 2. Column 3 reports the analogous estimate for log tract median household income, with standard errors in column 4. Column 5 reports the earnings-to-tract-income elasticity, computed as the ratio of column 3 to column 1. Column 6 reports the mean change in log household earnings over the eight-year period following ACS sampling. Columns 7–9 decompose mean neighborhood upgrading into earnings-driven and non-earnings components. Column 7 reports the portion of mean tract income growth explained by earnings growth, computed as the elasticity (column 5) times mean earnings growth (column 6). Column 8 reports the residual portion of mean tract income growth not explained by earnings growth. Column 9 reports the mean change in log tract median income, which equals the sum of columns 7 and 8. Race categories "White" and "Black" refer to non-Hispanic White and non-Hispanic Black individuals, respectively. All estimates use the coworker earnings shock sample described in Section 6.2. Shock estimates are scaled to reflect the effect of a 10 percent year-over-year increase in coworker earnings.
Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

Table 6: Pass-Through of a Hypothetical Place-Based Policy

	Exit probability		Expected earnings gain		
Exit response estimate	Untreated	Treated	Treatment−control	Place	Pass-through
Panel A: Homogeneous effect on earnings ($2,952 for all treated)					
Coworker shock estimate	0.517	0.534	$2,952	$1,296	0.439
No effect	0.517	0.517	$2,952	$1,426	0.483
Panel B: Concentrated effect on earnings (10% prob. of $29,520, 90% prob. of $0)					
Coworker shock estimate	0.517	0.694	$2,952	$826	0.279
No effect	0.517	0.517	$2,952	$1,426	0.483

Notes: This table reports back-of-the-envelope pass-through calculations following equation (10) for a hypothetical place-based policy with the same average earnings effect as Project QUEST (Roder and Elliott, 2021). Panel A assumes the treated individual gains $2,952. Panel B assumes a $29,520 gain with probability 0.1 and no gain with probability 0.9. Rows vary the assumed effect of earnings gains on exit from high-poverty neighborhoods, using either an estimate based on the coworker shock approach (footnote 38) or assuming no effect of the program on migration. In Panel B, treated exit probabilities are reported for individuals with the earnings gain; the exit probabilities for individuals with no earnings gain are the same as untreated individuals. The treatment minus control earnings gain is the denominator of equation (10) and the place earnings gain is the numerator.

Online Appendix

A Conceptual Framework: Derivations

This appendix derives the results in Section 2. Write systematic utility as

$$V_{ij}^{s} \equiv \ln(y_i - r_j) + \left(\beta_g + \delta_g \ln y_i\right) \ln(q_j) + a_{ij}, \tag{A.1}$$

so that the probability household i chooses neighborhood j is

$$P_j \equiv \Pr(j \mid y_i, a_i) = \frac{\exp\left(V_{ij}^{s}/\sigma_g\right)}{\sum_k \exp\left(V_{ik}^{s}/\sigma_g\right)}. \tag{A.2}$$

Throughout, expectations, variances, and covariances are taken across neighborhoods using the probability choice weights from (A.2) unless noted otherwise. That is, for any neighborhood-varying quantities x_j and z_j,

$$\mathbb{E}[x_j] \equiv \sum_j P_j\, x_j, \qquad \mathrm{Cov}(x_j, z_j) \equiv \sum_j P_j\, x_j z_j - \mathbb{E}[x_j]\,\mathbb{E}[z_j], \qquad \mathrm{Var}(x_j) \equiv \mathrm{Cov}(x_j, x_j), \tag{A.3}$$

with the weights P_j given by (A.2).

A.1 A Useful Identity

For any scalar θ that enters systematic utility, the response of expected neighborhood quality is the covariance, under the choice probabilities, between quality and the marginal effect of θ on utility,

$$\frac{\partial \ln q_i}{\partial \theta} = \frac{1}{\sigma_g} \mathrm{Cov}\left(\ln q_j,\ \frac{\partial V_{ij}^{s}}{\partial \theta}\right). \tag{A.4}$$

To see this, differentiate the logit probability (A.2),

$$\frac{\partial P_j}{\partial \theta} = \frac{P_j}{\sigma_g}\left(\frac{\partial V_j^{s}}{\partial \theta} - \sum_k P_k \frac{\partial V_k^{s}}{\partial \theta}\right), \tag{A.5}$$

and substitute into $\partial \ln q_i/\partial\theta = \sum_j \ln q_j\, \partial P_j/\partial\theta$, using that q_j is fixed:

$$\frac{\partial \ln q_i}{\partial \theta} = \frac{1}{\sigma_g}\left[\mathbb{E}\Big[\ln q_j \tfrac{\partial V_j^{s}}{\partial \theta}\Big] - \mathbb{E}[\ln q_j]\,\mathbb{E}\Big[\tfrac{\partial V_j^{s}}{\partial \theta}\Big]\right] = \frac{1}{\sigma_g}\mathrm{Cov}\Big(\ln q_j, \tfrac{\partial V_j^{s}}{\partial \theta}\Big). \tag{A.6}$$

We apply (A.4) repeatedly below.

A.2 Earnings Mobility

Differentiating V_j^s in (A.1) with respect to $\ln y_i$ gives

$$\frac{\partial V_j^s}{\partial \ln y_i} = \frac{y_i}{y_i - r_j} + \delta_g \ln(q_j). \tag{A.7}$$

Substituting into the result (A.4) and using linearity of covariance,

$$\frac{\partial \ln q_i}{\partial \ln y_i} = \frac{1}{\sigma_g}\left[\delta_g \operatorname{Var}(\ln q_j) + \operatorname{Cov}\left(\ln q_j, \frac{y_i}{y_i - r_j}\right)\right]. \tag{A.8}$$

Since $\delta_g > 0$, the first term is positive. The second is also positive: $y_i/(y_i - r_j)$ is increasing in r_j, and r_j is increasing in $\ln q_j$, so $y_i/(y_i - r_j)$ is increasing in $\ln q_j$, and the covariance of $\ln q_j$ with any increasing function of $\ln q_j$ is positive whenever quality varies. Hence $\partial \ln q_i/\partial \ln y_i > 0$.

Higher income leads households to leave poor neighborhoods. Let ℓ index households' initial neighborhood. From (A.5) with $\theta = \ln y$, the effect of a change in income on living in one's initial neighborhood is:

$$\frac{\partial \Pr(\ell \mid \cdot)}{\partial \ln y} = \frac{P_\ell}{\sigma_g}\left(\frac{\partial V_\ell^s}{\partial \ln y} - \mathbb{E}\Big[\frac{\partial V_j^s}{\partial \ln y}\Big]\right), \tag{A.9}$$

which is negative when $\partial V_\ell^s/\partial \ln y = y/(y - r_\ell) + \delta_g \ln(q_\ell)$ lies below its choice-weighted average—that is, when the initial neighborhood ℓ is a low-rent, low-quality neighborhood. Higher income then lowers the probability of residing in such a neighborhood, the comparative-statics counterpart of the selective migration discussed in the main text.

A.3 Non-earnings Mobility

The result (A.4) gives $\partial \ln q_i/\partial a_{ik} = \frac{1}{\sigma_g} P_k(\ln q_k - \ln q_i)$, and summing over a perturbation da_i,

$$\sum_k \frac{\partial \ln q_i}{\partial a_{ik}}\, da_{ik} = \frac{1}{\sigma_g}\sum_k P_k(\ln q_k - \ln q_i)\, da_{ik} = \frac{1}{\sigma_g}\operatorname{Cov}\big(\ln q_j, da_{ij}\big). \tag{A.10}$$

Combining this with the earnings response (A.8) gives the total change in expected neighborhood quality,

$$d \ln q_i = \frac{\partial \ln q_i}{\partial \ln y_i}\, d \ln y_i + \frac{1}{\sigma_g}\operatorname{Cov}\big(\ln q_j, da_{ij}\big), \tag{A.11}$$

which is equation (2) in the main text.

A.4 Individual Sorting and Neighborhood Earnings Growth

This appendix shows how the pass-through equation (6) depends on the underlying sorting elasticity characterized in equation (3). Our goal is to provide an intuitive connection between the household and neighborhood-level models, and we make several simplifying assumptions that serve this purpose.

As in Section 2.2, we consider exit from a high-poverty neighborhood between a baseline period $t = 0$ and a follow-up $t = 1$, defining the high-poverty neighborhood P as the set of

locations whose fixed quality q_j lies at or below a ceiling c. We define the *baseline cohort* C as the unit mass of individuals residing in P at $t = 0$.

To simplify notation, we let y_{i0} denote baseline *logged* earnings of resident i and y_{i1} denote their end line earnings, where the cohort means are denoted by $\bar{y}_0 = \mathbb{E}[y_{i0}]$ and $\bar{y}_1 = \mathbb{E}[y_{i1}]$. We also define individual i's earnings *growth* as $g_i = y_{i1} - y_{i0}$ with mean $\bar{g} = \mathbb{E}[g_i]$ and variance $v = \mathrm{Var}(g_i)$. We use log earnings in this section because it simplifies the exposition, but it is possible to derive similar results using levels. We further simplify notation by letting q_i denote expected quality in logs.

We linearize equation (2) and write the resident's realized-quality change as the sum of the income and non-income channels,

$$\Delta q_i = \eta\, g_i + \xi_i, \tag{A.12}$$

where ξ_i is the non-earnings preference shift, assumed to be independent of g_i. A baseline resident of P begins with quality $q_{i0} \leq c$ and exits the set of high-poverty neighborhoods if their chosen quality rises above the threshold c. Specifically, they exit P when:

$$q_{i0} + \eta\, g_i + \xi_i > c \iff \eta\, g_i > \underbrace{c - q_{i0} - \xi_i}_{d_i},$$

where $d_i \equiv c - q_{i0} - \xi_i$ is the distance to the exit margin net of the non-earnings preference shock. Let G_d be the c.d.f. of d_i across the cohort (with g_i independent of initial quality choice and the preference shock, $d \perp g$). Then, for an individual with earnings growth g_i, the probability of exiting is

$$\Pr(\text{Exit} \mid g_i) = \Pr(d_i < \eta\, g_i) = G_d(\eta\, g_i).$$

For exposition, we assume G_d is linear (i.e. uniform) over the empirically relevant range of d_i with constant density $m \equiv G_d'$, which yields:

$$\Pr(\text{Exit} \mid g_i) = \tau_0 + \eta\, m\, g_i, \qquad \tau_0 \equiv G_d(0) \tag{A.13}$$

The intercept τ_0 is the average move rate absent earnings growth, reflecting non-earnings, match-driven moves. The slope, which corresponds to the earnings gradient in Figure 3, Panel B, is the product of the structural sorting elasticity η and the local density m of residents on the margin of moving.

With this set-up, we can characterize both how the exit rate and the resulting earnings composition of residents depend on η. First, the aggregate exit rate depends on η and the *average* earnings growth:

$$\tau \equiv \Pr(\text{Exit}) = \mathbb{E}[\tau_0 + \eta\, m\, g_i] = \tau_0 + \eta\, m\, \bar{g}. \tag{A.14}$$

Higher average earnings growth among the initial cohort leads to higher exit rates, with η governing the relationship between average earnings and turnover.

A higher sorting elasticity η also changes the *composition* of exiters between those leaving due to preference shocks and those leaving due to earnings growth. For any characteristic, the resulting selection can be characterized as follows:

Lemma 1 (Selection)**.** *Under* (A.13)*, for any resident characteristic* X_i*,*

$$\mathbb{E}[X_i \mid \textit{Exit}] = \bar{X} + \frac{\eta m}{\tau}\operatorname{Cov}(X_i, g_i), \qquad \mathbb{E}[X_i \mid \textit{Stay}] = \bar{X} - \frac{\eta m}{1-\tau}\operatorname{Cov}(X_i, g_i).$$

Proof. $\mathbb{E}[X_i \mid \text{Exit}] = \mathbb{E}[X_i\,(\tau_0 + \eta m g_i)]/\mathbb{E}[\tau_0 + \eta m g_i]$, where the denominator is equal to τ by equation (A.14). Using equation (A.14) again, one can rewrite $\tau_0 + \eta m g_i = \tau + \eta m(g_i - \bar{g})$ and use this to write the numerator as $\tau\bar{X} + \eta m\,\mathbb{E}[X_i(g_i - \bar{g})] = \tau\bar{X} + \eta m\operatorname{Cov}(X_i, g_i)$, using $\mathbb{E}[X_i(g_i - \bar{g})] = \operatorname{Cov}(X_i, g_i)$. This gives the result for exiters. For stayers, the proof formula is the same but replacing $\tau_0 + \eta m g_i$ with $(1 - \tau_0) - \eta m g_i$ □

Applying Lemma 1 to growth g_i (and noting $\operatorname{Cov}(g_i, g_i) = v$), the average earnings growth of exiters and stayers is:

$$\mathbb{E}[g_i \mid \text{Exit}] = \bar{g} + \frac{\eta m v}{\tau}, \qquad \mathbb{E}[g_i \mid \text{Stay}] = \bar{g} - \frac{\eta m v}{1-\tau}. \tag{A.15}$$

When there is dispersion in earnings growth rates, a higher η shifts the composition of exiters towards individuals with particularly high earnings growth (and conversely for stayers).

The resulting implications for endline earnings of stayers and exiters depend on whether earnings growth is systematically correlated with baseline earnings levels; Lemma 1 is sufficiently general to account for such covariance. However, if one assumes for simplicity that earnings growth is independent of baseline levels so that $E[y_{i0} \mid \text{Exit}] = E[y_{i0} \mid \text{Stay}] = E[y_{i0}]$, then endline earnings follow the same selection rule as growth:

$$\mathbb{E}[y_{i1} \mid \text{Exit}] = \bar{y}_1 + \frac{\eta m v}{\tau}, \qquad \mathbb{E}[y_{i1} \mid \text{Stay}] = \bar{y}_1 - \frac{\eta m v}{1-\tau}. \tag{A.16}$$

To study the evolution of *neighborhood* mean earnings, it is necessary to specify the rate and composition of entrants. We make two simplifying assumptions for exposition. First, the average earnings of entrants $\bar{y}_1^{\text{entr}}$ is exogenous and does not depend on η. Second, we assume the neighborhood is of fixed size or in steady-state so that the measure of entrants is equal to the measure of exiters τ. With these assumptions, one can express the endline *cohort* average log earnings level as a weighted average of stayers and leavers,

$$\bar{y}_1^{\text{cohort}} = \bar{y}_1 = (1-\tau)\,\mathbb{E}[y_{i1} \mid \text{Stay}] + \tau\,\mathbb{E}[y_{i1} \mid \text{Exit}].$$

The *neighborhood* endline average is likewise a weighted average:

$$\bar{y}_1^{\text{place}} = (1-\tau)\,\mathbb{E}[y_{i1} \mid \text{Stay}] + \tau\,\bar{y}_1^{\text{entr}}.$$

Combining these, the gap between the cohort and neighborhood endline earnings can be expressed as

$$\bar{y}_1^{\text{place}} = \bar{y}_1^{\text{cohort}} + \tau\big(\bar{y}_1^{\text{entr}} - \bar{y}_1^{\text{exit}}\big), \qquad \bar{y}_1^{\text{exit}} \equiv \mathbb{E}[y_{i1} \mid \text{Exit}]. \tag{A.17}$$

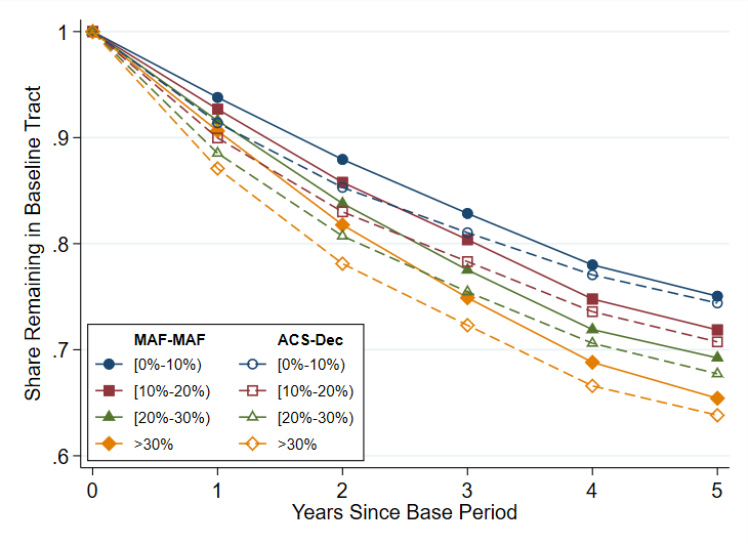

This can be used to write the neighborhood earnings change in terms of underlying parameters:

$$\Delta\bar{y}^{\text{place}} = \Delta\bar{y}^{\text{cohort}} + \underbrace{\big(\tau_0 + \eta m\bar{g}\big)\big(\bar{y}_1^{\text{entr}} - \bar{y}_1^{\text{cohort}}\big)}_{\text{Turnover Rate}} - \underbrace{\eta m v}_{\text{Selection of Exiters}}. \tag{A.18}$$

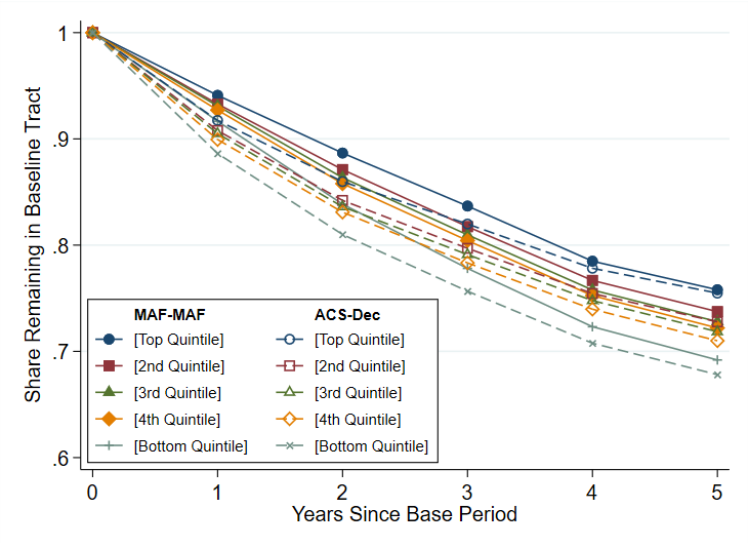

This final expression shows that the elasticity η leads average neighborhood earnings to grow slower than average cohort earnings through two channels. First, whenever the mean earnings of entrants is lower than the average endline mean earnings of initial cohort residents, higher η reduces neighborhood earnings through higher turnover of initial residents. Second, higher η further reduces neighborhood earnings growth when there is dispersion in earnings growth rates across initial residents as incumbents with high earnings growth become a larger share of exiters.

Figure A.1: Share of Individuals Remaining in Baseline Tract (MAFARF Validation)

(a) By Baseline Tract Poverty Rate Category

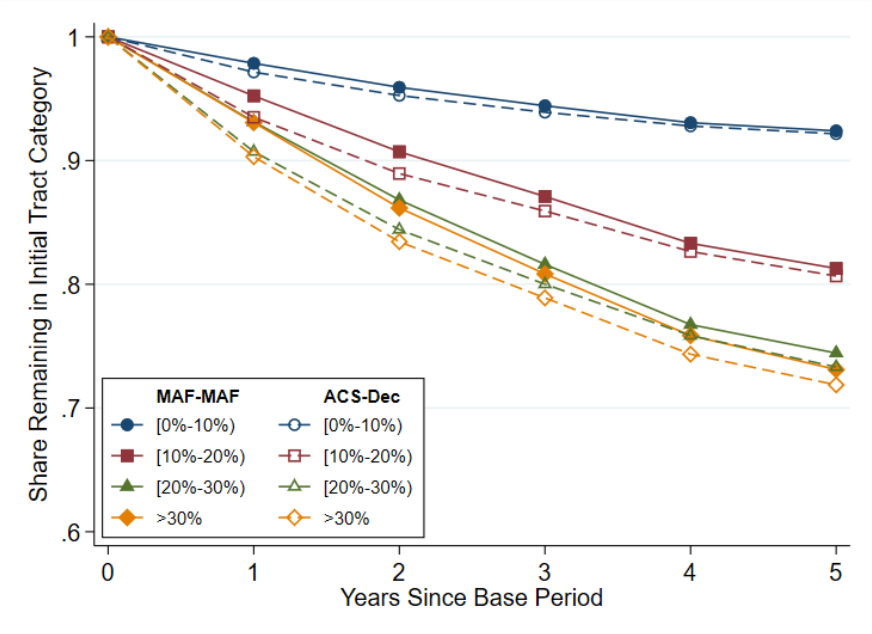

(b) By Baseline Tract Income Quintile

Notes: This figure recreates Figure 2 comparing tract locations drawn from the MAFARF to those drawn from 2005–2009 ACS surveys at baseline and the 2010 decennial census at endline. This figure shows the share of individuals who live in their baseline census tract for 1 to 5 years after the baseline year (the year an individual is sampled in the ACS). Individuals are stratified based on the baseline tract's poverty rate (Panel A) or quintile of median household income (Panel B). The solid lines correspond to the census tract measured by the MAFARF at both the baseline and endline (2010). The dashed lines correspond to the census tract being measured by the ACS at baseline and the 2010 decennial census at endline. Unlike Figure 2, each dot represents a different cohort of individuals; i.e., 1 year since baseline consists of those who responded to the ACS in 2009, 2 years since baseline consists of those who responded to the ACS in 2008, and so on.

Source: Authors' calculations using data from the ACS, MAFARF, and the 2010 decennial census.

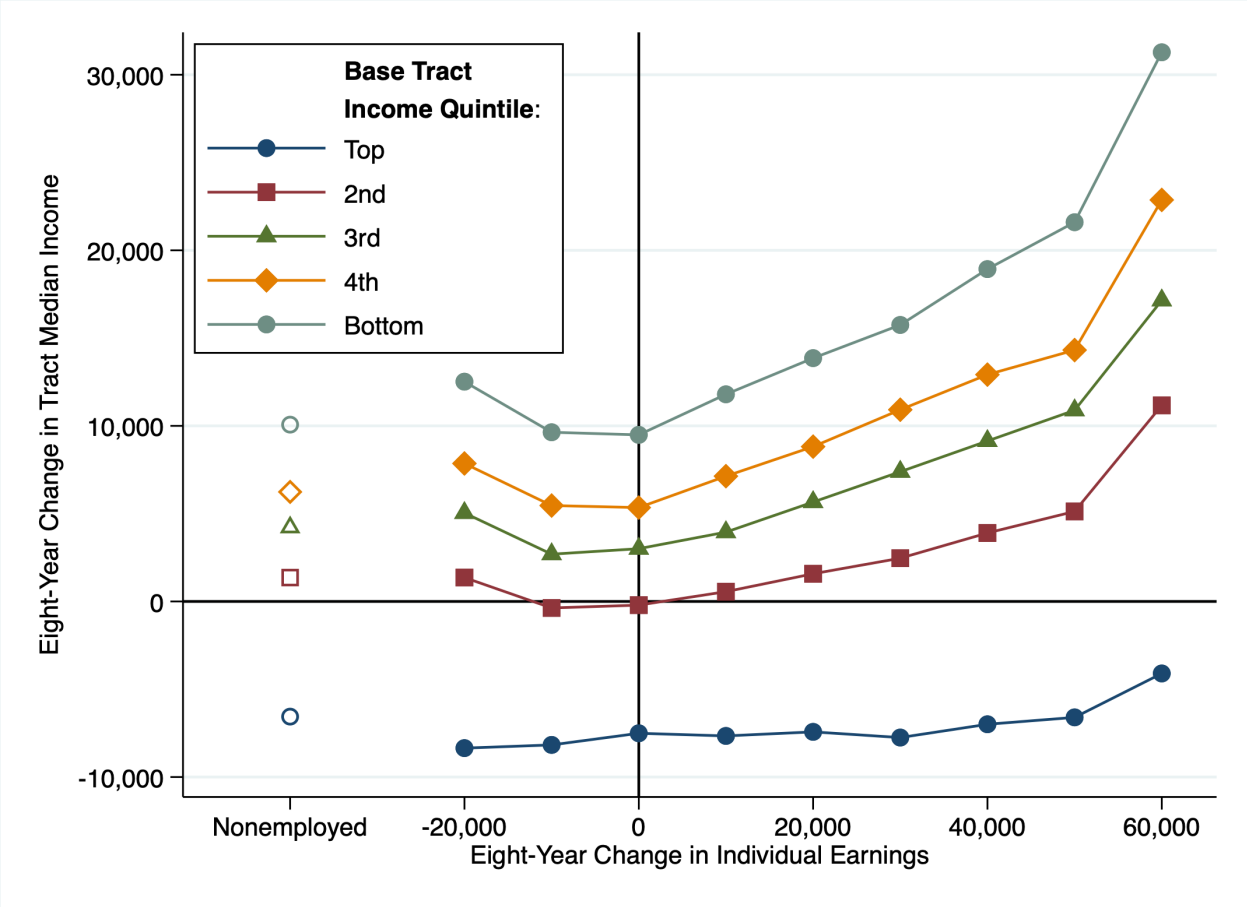

Figure A.2: Share of Individuals Remaining in Baseline Tract Category (MAFARF Validation)

Notes: This figure validates the diagonal of Panel A of Tables 3 and A.4, comparing the share of individuals remaining in their baseline tract poverty rate category as measured by the MAFARF to that measured using the 2005–2009 ACS at baseline and the 2010 decennial census at endline. This figure shows the share of individuals who remain in the same tract poverty rate category for 1 to 5 years after the baseline year (the year an individual is sampled in the ACS). Individuals are stratified by the baseline tract's poverty rate category, as defined in Table 3. The solid lines correspond to the tract poverty category being measured from the MAFARF at both baseline and endline (2010). The dashed lines correspond to the tract poverty category being measured by the ACS at baseline and the 2010 decennial census at endline. As in Figure A.1, each dot represents a different cohort of individuals; i.e., 1 year since baseline consists of those who responded to the ACS in 2009, 2 years since baseline consists of those who responded to the ACS in 2008, and so on.

Source: Authors' calculations using data from the ACS, MAFARF, and the 2010 decennial census.

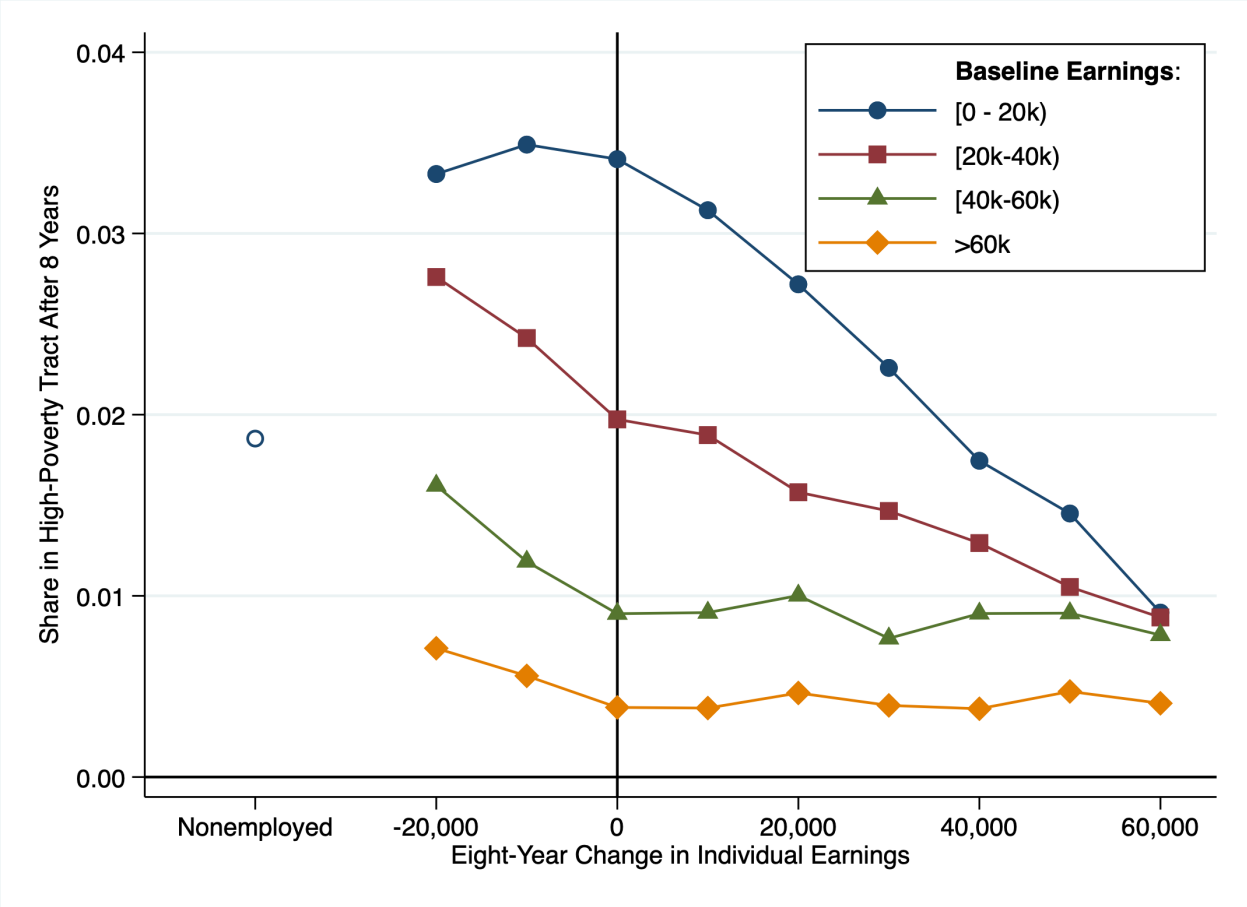

Figure A.3: Tract Mobility and Earnings Mobility, By Initial Neighborhood Income Quintile

Notes: Figure replicates Panel A of Figure 3 stratifying individuals by quintiles of the median household income of their baseline tract instead of by the poverty rate. See note to Figure 3 for further details.

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

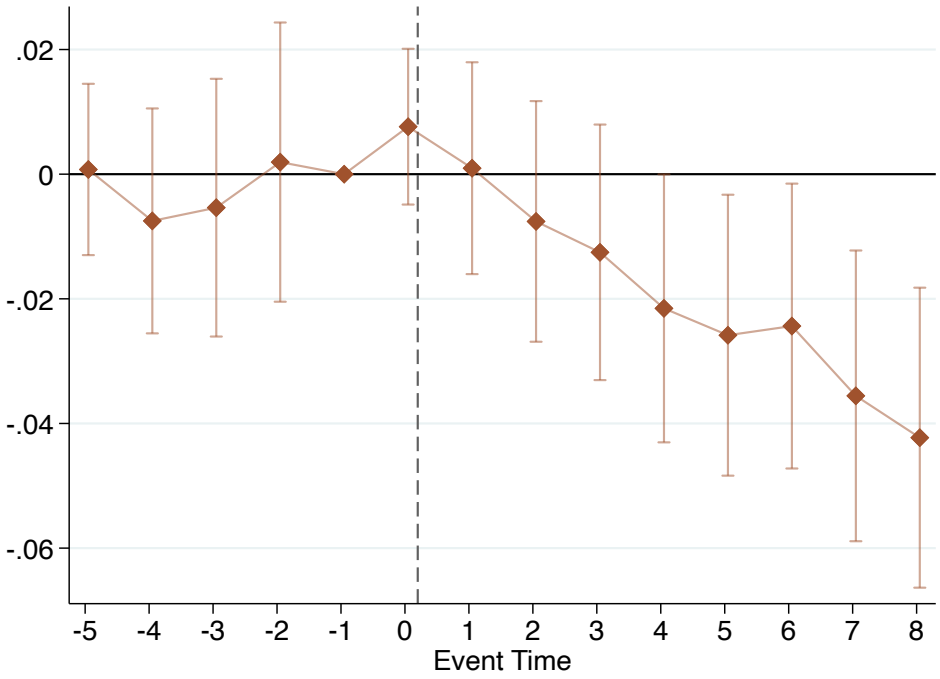

Figure A.4: Entry Into High Poverty Neighborhoods, By Baseline Individual Earnings

Notes: Figure replicates Panel C of Figure 3 stratifying individuals initially living outside of high-poverty neighborhoods (those with baseline poverty rates below 30 percent) by their own individual baseline earnings instead of by their initial neighborhood characteristics. See note to Figure 3 for further details.

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

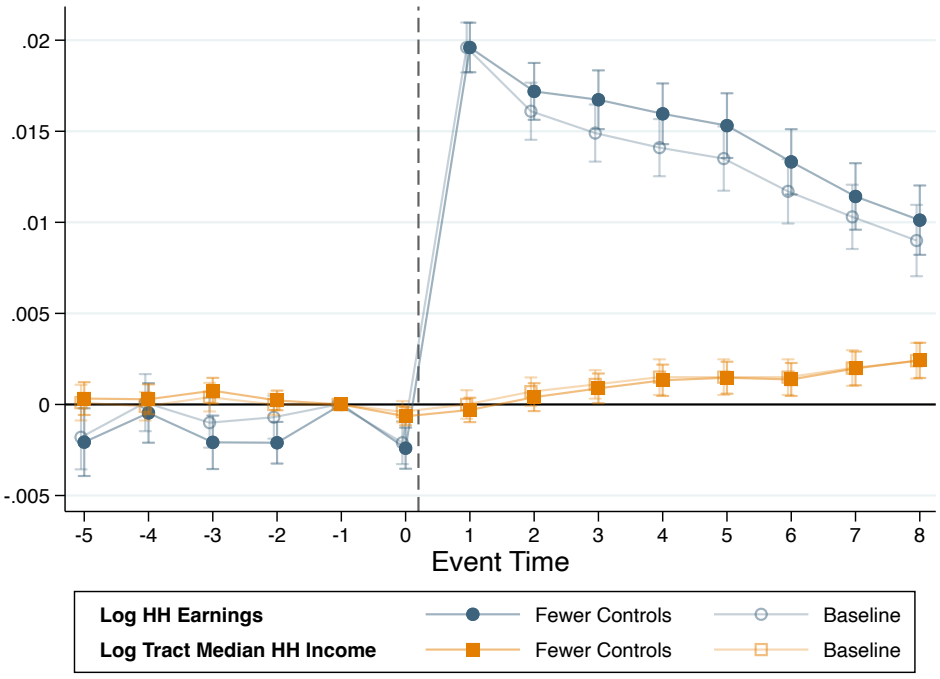

Figure A.5: Effect of a Coworker Earnings Shock on Neighborhood Poverty Rate

Notes: This figure displays OLS estimates of equation (7) with 95 percent confidence intervals. The figure uses a subset of the earnings sample consisting of individuals working at firms with at least 25 employees in the holdout sample, as described in Section 6.2. Effects are scaled so that coefficients can be interpreted as the effect of a 10 percent increase in coworker quarterly earnings over a four-quarter period that begins when an individual is sampled in the ACS. The outcome is the poverty rate measured in percentage points (0–100 scale) in the tract where individuals reside in each year. Standard errors are clustered at the firm level.

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

Figure A.6: Effect of a Coworker Earnings Shock: Fewer Controls

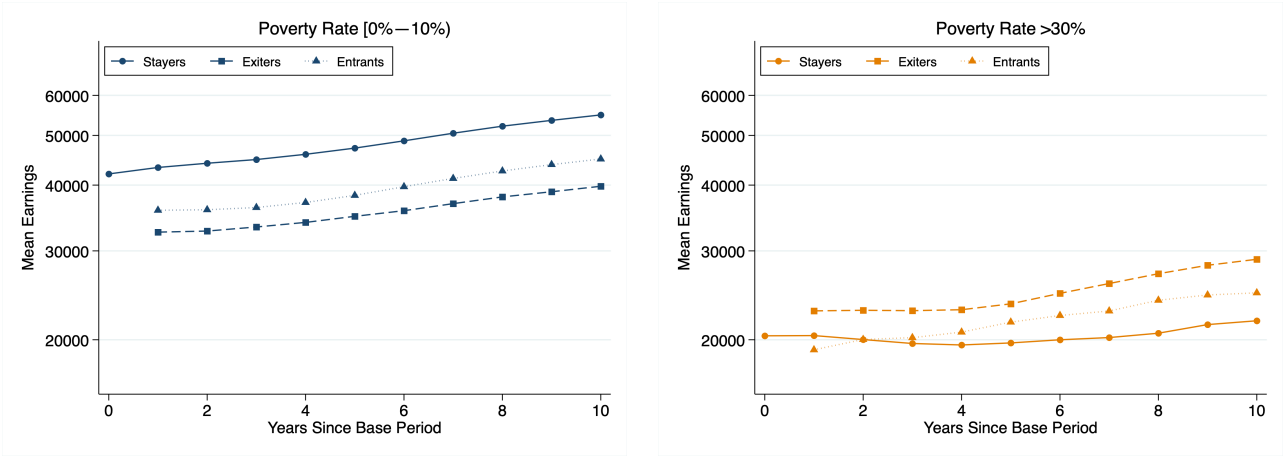

Notes: This figure replicates the event-study estimates of the effect of coworker earnings shocks on log household earnings and log tract median household income in Figure 5, both under the original specification (lighter shades, hollow markers) and under a specification with fewer controls (darker shades, filled markers). The "Fewer Controls" specification limits controls to only industry, initial wage, initial tract income, and age. In contrast to the baseline specification, the "Fewer Controls" specification excludes state and CBSA fixed effects as well as firm-level controls. The exact regression for the "Fewer Controls" specification is

$$Y_{i,t} = \mu_i + \sum_{k \in \mathcal{E}} \beta_k \text{PayShock}_i \times \mathbb{1}[t = a(i) + k] + \theta_{t,a(i)} + \omega_{t,a(i),n(i)} + \sum_{k \in \mathcal{E}} X_i' \alpha_{a(i),k} \times \mathbb{1}[t = a(i) + k] + \epsilon_{i,t,k},$$

where $a(i)$ refers to the year that individual i first appears in the ACS. We control for common trends among individuals sampled in the same ACS year over time using the fixed effects $\theta_{t,a(i)}$, which capture the interaction between the ACS year of observation ($a(i)$) and the outcome year (t). The fixed effects $\omega_{t,a(i),n(i)}$ allow trends in outcomes to vary arbitrarily based on individuals' baseline 2-digit NAICS industry codes ($n(i)$) and ACS year of observation ($a(i)$). X_i is a limited vector of individual controls, which are interacted with relative time dummies and allowed to vary across cohorts of individuals sampled in the ACS in different years $a(i)$. These controls are indicator variables for quintiles of initial hourly wage, initial tract income, and age.

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

Figure A.7: Earnings Growth Among Stayers, Exiters, and Entrants, by Tract Poverty Level

Notes: This figure shows the mean earnings in each year for stayers, entrants, and exiters from different types of tracts. These categories are determined relative to individuals' neighborhood type in the baseline year. For example, entrants to high-poverty neighborhoods in year six are defined as people who lived in this neighborhood type in year six but not year zero. As in Figure 6, the exercise uses the earnings sample and further restricts to the 1965 to 1980 birth cohorts (to minimize the role of retirement and sample entry). The y-axis is on a log scale.

Source: Authors' calculations using data from the ACS, MAFARF, and LEHD.

Table A.1: Summary Statistics

	(1) Migration sample	(2) Earnings sample	(3) Coworker earnings shock sample
Demographics

Baseline tract poverty rate			
0–10%	0.549	0.600	0.646
10–20%	0.288	0.263	0.231
20–30%	0.106	0.091	0.081
30+%	0.057	0.046	0.041

Notes: This table reports means of individual and household characteristics across the three samples used in the paper: the migration sample, the earnings sample, and the coworker earnings shock sample. The construction of these samples is described in Sections 3.2 and 6.2. All variables correspond to the baseline year (when people are sampled in the ACS). Income variables are drawn from the ACS and deflated to 2019 dollars using the CPI. Tract poverty rates are calculated from the 2005–2009 ACS.

Individuals	13,230,000	13,230,000	13,230,000
R-squared	0.003	0.019	0.105
CBSA and year FE		X	X
Individual controls			X

Notes: This table reports regressions in which the dependent variable is an indicator for whether the person moves away from their baseline tract over the eight-year period that starts when an individual is sampled in the ACS. The key explanatory variables of interest are indicators for the 2005–2009 poverty rate of the neighborhood where an individual is observed at the start of the eight-year period; the omitted indicator is for the poverty rate above 30 percent. Columns 2 and 3 include CBSA and year fixed effects. Column 3 also includes fixed effects for individual race, ethnicity, age, and baseline education. Standard errors, clustered at the level of the baseline tract, are reported in parentheses.

Source: Authors' calculations using data from the ACS and MAFARF.

Table A.4: One-Year Transition Rates Across Neighborhood Types

Panel A: Neighborhood poverty rate

	Year $t+1$			
Year t	0–10	10–20	20–30	30+
0–10	97.2	2	0.5	0.2
10–20	4.2	94	1.2	0.6
20–30	3.5	3.7	91.5	1.3
30+	2.7	3.4	2.7	91.2

Panel B: Quintile of neighborhood median income

	Year $t+1$				
Year t	1	2	3	4	5
1	93.5	2.6	1.9	1.3	0.7
2	2.1	93.1	2.1	1.7	1
3	1.3	1.8	93.3	2.1	1.4
4	0.8	1.2	1.8	94	2.2
5	0.4	0.7	1.1	1.9	96

Notes: Table reports the share of people who start in each type of neighborhood in year t (the year they are sampled in the ACS) that end up in each type of neighborhood in year $t+1$. We classify census tracts based on 2005–2009 poverty rates in Panel A and population-weighted quintiles of the 2005–2009 median household income distribution in Panel B. This exercise uses the migration sample, as described in Section 3.2.

Source: Authors' calculations using data from the ACS and MAFARF.

Table A.5: Regression of Migration across Income Quintiles on Baseline Neighborhood Income

	(1)	(2)	(3)

	(0.001)	(0.001)	(0.001)
Quintile 4	-0.007	-0.048	-0.041
	(0.001)	(0.001)	(0.001)
Quintile 5	-0.091	-0.143	-0.129
	(0.001)	(0.001)	(0.001)
Intercept	0.282	0.309	0.303
	(0.001)	(0.001)	(0.001)
Individuals	13,230,000	13,230,000	13,230,000
R-squared	0.009	0.024	0.071
CBSA and year FE		X	X
Individual controls			X

Notes: This table reports regressions in which the dependent variable is an indicator for whether the person moves over the eight-year period that starts when an individual is sampled in the ACS to a neighborhood in a different population-weighted quintile of 2005–2009 median household income. The key explanatory variables of interest are indicators for the population-weighted quintile of 2005–2009 median household income of the neighborhood where an individual is observed at the start of the eight-year period; the omitted indicator is for the first quintile. Columns 2 and 3 include CBSA and year fixed effects. Column 3 also includes fixed effects for individual race, ethnicity, age, and baseline education. Standard errors, clustered at the level of the baseline tract, are reported in parentheses.

Source: Authors' calculations using data from the ACS and MAFARF.

Table A.6: Characteristics of Entrants, Exiters, and Stayers in High-Poverty Neighborhoods

	(1) Entrants	(2) Exiters	(3) Stayers	(4) Rest of sample
Mean age	42.76	42.69	51.66	51.85
Share under 30	0.197	0.194	0.081	0.066
Share white	0.519	0.492	0.464	0.818
Share with no college	0.578	0.574	0.652	0.402
Share married family	0.359	0.403	0.439	0.657
Share with child under 18	0.468	0.503	0.399	0.372
Share renter	0.725	0.679	0.478	0.227
Share not in labor force	0.299	0.283	0.404	0.320
Share unemployed	0.098	0.084	0.061	0.035
Share in poverty	0.300	0.260	0.264	0.075
Mean individual earnings ($)	23,150	24,880	19,920	39,420
Mean household income ($)	53,450	57,990	52,090	100,800
Share in high-poverty in $t + 10$	0.371	0.156	0.647	0.015

Notes: This table reports the mean characteristics of four groups, defined by whether they lived in a high-poverty neighborhood in each of two consecutive years. The baseline year is the year an individual was sampled in the ACS, and the follow-up period is the next year. Entrants did not live in a high-poverty tract (defined as a rate over 30 percent) in the baseline year but did in the following year. Exiters made the opposite move, while stayers lived in a high-poverty neighborhood in both years. Column 4 consists of all remaining individuals in the migration sample. All characteristics are drawn from ACS responses, except the share in a high-poverty tract 10 years after the ACS year, which is taken from the MAFARF.

Source: Authors' calculations using data from the ACS and MAFARF.

Table A.7: Effects of Coworker Earnings Shocks Among Individuals in High-Poverty Tracts

	(1) Effect on earnings (HH)	(2) SE	(3) Effect on tract outcome	(4) SE	(5) Δ earnings (HH)	(6) Δ tract out. earnings component	(7) Δ tract out. non-earnings component	(8) Δ tract outcome total

No children	0.0158	0.0032	0.0021	0.0024	0.0558	0.0074	0.2588	0.2662
Panel B: Tract outcome: Tract poverty rate								
Pov. rate 20+%	0.0129	0.0020	−0.0916	0.0448	0.0790	−0.5593	−7.2607	−7.82
Renter	0.0167	0.0032	−0.1482	0.0713	0.1205	−1.0700	−8.6030	−9.67
Owner-occupant	0.0085	0.0025	−0.0368	0.0565	0.0471	−0.2030	−6.1940	−6.40
Has children	0.0104	0.0026	−0.1202	0.0584	0.0954	−1.1053	−6.1227	−7.23
No children	0.0158	0.0032	−0.0329	0.0707	0.0558	−0.1163	−8.5437	−8.66

Notes: This table reports heterogeneity in the effects of coworker earnings shocks on household earnings and neighborhood choice among individuals residing in tracts with a poverty rate above 20 percent. Estimates are based on a variant of equation (7) that pools periods into a pre-shock period, a short-run post period ($k \in [1, 3]$), and a long-run post period ($k \in [4, 8]$); the table reports the $k \in [4, 8]$ coefficient throughout. Column 1 reports the pooled estimate of the coworker pay shock on log household LEHD earnings, with standard errors clustered at the firm level in column 2. Column 3 reports the analogous estimate for the neighborhood outcome, with standard errors in column 4; in Panel A the outcome is log tract median household income, and in Panel B it is the tract poverty rate in percentage points (0–100 scale). Column 5 reports the mean change in log household earnings over the eight-year period following ACS sampling. Columns 6–8 decompose mean neighborhood change into earnings-driven and non-earnings components. Column 6 reports the portion of mean neighborhood change explained by earnings growth, computed as the ratio of column 3 to column 1 times mean earnings growth (column 5). Column 7 reports the residual portion not explained by earnings growth. Column 8 reports the mean change in the neighborhood outcome, which equals the sum of columns 6 and 7. All estimates use the coworker earnings shock sample described in Section 6.2. Shock estimates are scaled to reflect the effect of a 10 percent year-over-year increase in coworker earnings.
