Battle of the Forecasts: Mean vs. Median as the Survey of Professional Forecasters' Consensus

By **Fatima Mboup** and Ardy Wurtzel

Over the 32 years that the Federal Reserve Bank of Philadelphia has been conducting the widely followed Survey of Professional Forecasters (SPF), our analysis of the results of each new quarterly survey has emphasized the median forecast as a measure of the consensus projection.¹ The median—which we compute as the middle projection of approximately 40 individual forecasts for a broad array of major macroeconomic indicators—has proved to be a popular benchmark against which alternative forecasts can be judged. However, the median is not the only reasonable choice for a consensus projection. We could also use as the consensus the simple arithmetic average, or mean. Yet, we have avoided that approach because the mean projection is particularly sensitive to any extreme projections from our panelists. Because extreme individual responses could produce inaccurate consensus forecasts, using the mean could potentially harm the overall reliability and usefulness of the survey's projection. That said, however, we have never formally tested our assumption in a statistically rigorous and comprehensive manner.

In this Research Brief, we study whether the accuracy of the median forecast in fact exceeds that of the mean forecast. Because we want the results of our study to be as robust as possible, we examine the forecasts for six important survey variables over five forecast horizons, using four alternative measures of the realizations from which we compute the forecast errors, and four alternative sample periods. We apply the well-known Diebold–Mariano (1995) statistical test for relative forecast accuracy between the mean and median consensus projections.

Overall, our analysis shows some statistically significant differences between the accuracy of the mean and median forecasts, with the mean

forecasts more often exhibiting marginally higher levels of accuracy. However, these differences in accuracy, when they exist, are small and negligible. Moreover, because our results are sensitive to the variable, forecast horizon, sample period, and measure for the realizations, we conclude that the SPF median forecast remains a useful measure of the consensus projection when we factor in its benefits in guarding against typographical errors in the panelists' forecast submissions.²

Real-Time Methodological Considerations

In studying the relative accuracy of the SPF mean and median projections, we pay particular attention to the real-time nature of our statistical experiments. The survey itself is conducted in real time, not after the fact, and the panelists' projections are, accordingly, based on the macroeconomic information they had when they formulated their projections. Moreover, the Philadelphia Fed does not change the consensus projections after the survey date.³ The real-time nature of the survey's forecasts suggests that we must exercise some caution in our choice of the historical realizations against which we will assess forecast accuracy.

It is well known that U.S. government statistical agencies frequently revise the historical realizations that we use to compute our forecast errors. These data revisions suggest that our findings could be sensitive to the measure we choose to represent the realizations. We account for revisions to the historical realizations by considering alternative measures of the realizations, depending on the degree of revision to which the realization is subject. Our four measures for the realizations are, alternatively, the first, second, and third release values published by the statistical agencies and the values as we know them today.⁴

Because the SPF began in 1968,⁵ we focus our analysis on the period from 1968 to 2016, the latter date corresponding with the last observation available when we computed our results. We think our focus on the full sample period is important in our study because much previous academic work has focused on this period using the median projection and we want to document differences in forecast accuracy between mean and median projections over the

² It is worth noting that, although the Philadelphia Fed focuses on the median projections in our analysis of each survey's results, we provide the survey's entire history of mean projections as well as median projections at www.philadelphiafed.org/research-and-data/real-time-center/survey-of-professional-forecasters/data-files.

³ When we discover a typographical error in our data set, sometimes well after the survey date, we adjust the data appropriately. Such occurrences are rare and almost always have minor effects on the consensus projections.

⁴ Our realizations come from the Philadelphia Fed's real-time data set for macroeconomists at www.philadelphiafed.org/research-and-data/real-time-center/real-time-data.

⁵ The Philadelphia Fed has conducted the SPF since the second quarter of 1990. From its inception in 1968 through 1990, it was conducted by the American Statistical Association (ASA) and the National Bureau of Economic Research (NBER). The results of the survey are monitored by policymakers, research economists, and business analysts around the world for its near-term outlook for the U.S. economy, as seen by a panel of professional forecasters who closely follow economic developments and generate their projections using both formal mathematical models and subjective judgments.

same period.⁶ At the same time, good reasons exist for considering additional periods for the analysis. We also compare the period over which the National Bureau of Economic Research (NBER) and the American Statistical Association (ASA) conducted the survey (1968 to 1990) with the period over which the Philadelphia Fed has been in charge of the survey (1991 to 2016). We distinguish between these periods because we want to control for rounding errors in the underlying forecast data under the NBER's tenure and we want to allow for the possibility that the Philadelphia Fed's tenure marks one of increased attention to typographical errors and other mistakes in the survey's responses. Finally, we have a particular interest in the period from 2005 to 2016 because it covers the most recent forecasts as well as the Great Recession and the subsequent recovery, a period over which one could reasonably expect some forecasters to submit extreme forecasts that could drive an interesting wedge between the consensus mean and median projections.

The SPF itself has evolved over time. Of the 23 variables currently in the survey, only a handful appeared in the survey in 1968. Because our interest includes the entire history of the SPF, we focus on those variables with the longest history in the survey: nominal GDP, the GDP price index, industrial production, real GDP, unemployment rate, and housing starts. The forecast horizons cover the current quarter and the following four quarters.⁷

The Mean-Square Error as a Measure of Forecast Accuracy

Our tests for the relative accuracy of the SPF's mean and median consensus forecasts follow the methodology of Stark (2010) in using the conventional mean-square-error (MSE) statistic, which we define as

$$mse_j(\tau, r) = \frac{1}{T} \sum_t \left(\varepsilon_{j, t+\tau|t}^{(r)} \right)^2, \quad \tau = 0, \dots, 4; \quad r = 1, \dots, 4; \quad j = 1, 2$$

where $\varepsilon_{j, t+\tau|t}^{(r)}$ is the τ -quarter-ahead forecast error, defined on the r^{th} measure of the realization; j is an index to distinguish between mean and median forecasts; and T measures the number of forecast errors in the sample period. The MSE is a popular summary statistic because it gives equal consideration to two undesirable properties of forecast errors: bias and variance. Indeed, a large MSE reflects either a large bias from zero in the forecast error or a large forecast error variance, or both, and signals poor forecast accuracy.

The Diebold–Mariano statistic forms the centerpiece for testing our null hypothesis that the MSE for the SPF mean forecast (mse_1) equals the MSE for the SPF median forecast (mse_2). Formally, we follow Diebold and Mariano (1995) in designing the null and alternative hypotheses as

⁶ A bibliography of academic papers using the survey's data is available at www.philadelphiafed.org/surveys-and-data/real-time-data-research/spf-academic-bibliography.

⁷ The forecasts for real GDP, nominal GDP, the GDP price index, and industrial production are expressed as quarter-over-quarter growth rates, compounded quarterly and expressed in annualized percentage points. (The level of the quarterly industrial production index is the quarterly average of the underlying monthly levels.) The forecasts for the quarterly average of monthly housing starts and the quarterly average of monthly unemployment rates are in millions of units and percentage points, respectively.

$$H_0 : mse_1(\tau, r) = mse_2(\tau, r)$$

$$H_1 : mse_1(\tau, r) \neq mse_2(\tau, r)$$

where, as noted above, we conduct a separate test for each variable, forecast horizon ($\tau = 0, 1, \dots, 4$), realization ($r = 1, \dots, 4$), and sample period.

Statistical Findings

We begin with a quick inspection of the qualitative differences between the mean and median forecasts at the two-quarters-ahead horizon. Figure 1 presents scatter plots of the median forecasts (x-axis) against the mean forecasts (y-axis) for each variable. The two-quarters-ahead horizon is representative of the additional horizons that we examined. A 45-degree line defines the locus along which the two forecasts are identical. Points above the locus indicate that the median forecast exceeds the mean forecast, while points below the locus indicate that the mean forecast exceeds the corresponding median forecast. We also distinguish between the consensus forecasts derived during the NBER's tenure in conducting the survey (1968 to 1990; light blue dots) and those derived during the Philadelphia Fed's tenure (1991 to 2016; dark blue dots).

The figure suggests three notable features in the SPF forecast data. First, most points cluster just above and below the 45-degree line, suggesting that the mean and median forecasts are close to each other but not identical. Second, for most variables, the differences between the mean and median forecasts, measured by the distance between the points and the 45-degree locus, seem greatest during the NBER's tenure in conducting the survey. Third, the differences between the mean and median forecasts are often greatest at the extreme values of the forecasts. It is also notable that at longer forecast horizons (not shown) we find larger differences between the mean and median projections, and the differences seem to grow with the horizon.⁸

Turning now to the formal statistical evidence, our Diebold–Mariano tests detected some statistically significant differences between the accuracy of the mean and median forecasts. However, the differences were almost always small. Tables 1 through 6 summarize our statistical findings separately for each variable, showing the number of times we rejected our null hypothesis of MSE equality between the mean and median forecasts. We computed counts separately for the cases in which the median forecast was more accurate than the mean and for the cases in which the mean forecast was more accurate.⁹ We conducted a total of 420 Diebold–Mariano tests in our analysis. Our summary tables show that when a statistically significant difference exists between the mean and median forecasts, the mean forecast was superior 69 times, while the median was superior 25 times.

⁸ These results are available upon request.

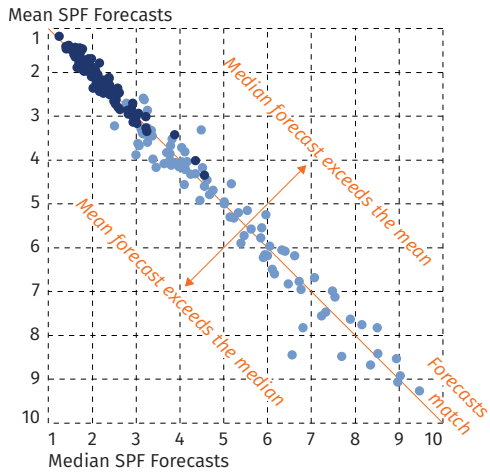

⁹ Our Diebold–Mariano statistics reflect the usual heteroscedasticity and autocorrelation consistent (HAC) correction using a rectangular window and truncation lag parameter of four quarters. We employ a 10 percent significance level.

Note: MSE1 is the mean-square error for the mean SPF forecasts, while MSE2 is the mean-square error for the median SPF forecasts.

Taking a closer look at our results for the real GDP projections in Table 4, we note that, when a statistically significant difference exists between the mean and median forecasts, the mean forecasts are superior in eight cases versus in five cases in the median forecasts. Over the entire sample period, 1968Q4 to 2016Q4, we found six cases of a statistically significant difference between the mean and median forecasts for real GDP, where the mean forecast was superior four times. For the most recent period, from 2005Q1 to 2016Q4, we found two cases of a statistically significant difference between the mean and median forecasts for real GDP, and, for all the cases, the median forecast was superior.¹⁰

When we look at Tables 1 through 6 collectively, we see that the mean projections seem to be more accurate more often than not. The variables nominal GDP and GDP price index lead the charge in cases where the mean is superior. Table 1 shows that for nominal GDP we found 24 statistically significant cases in which the mean was more accurate than the median but only two cases in which the median was more accurate than the mean. Similarly for the GDP price index, in Table 2 we found 21 cases in which the mean projections were superior and no cases for when the median projections were superior. Despite there being some statistically significant differences between the mean and median forecasts, a close inspection of the detailed results suggests the differences are usually small and economically insignificant.

Tables 3 through 6 show fewer cases of statistically significant differences between the mean and median projections in comparison with the results shown in Tables 1 and 2. Moreover, the differences between mean-square-errors for mean and median projections for industrial production, real GDP, unemployment rate, and housing starts are also very small and economically insignificant.¹¹ For example, we see in Table 7 that for the representative case of realizations measured by their final-release values in the sample period from 1968 to 1990, the percent differences in the root mean square error (RMSE) are mostly small and statistically insignificant. The percent difference in RMSE for all other variables regardless of horizon, sample period, and realization are also mostly economically small and statistically insignificant.

Conclusion

The Philadelphia Fed has always emphasized the SPF's median projection as the appropriate measure of the survey's consensus forecast. In this Research

¹⁰ An interesting question we do not address in this paper is whether relative forecast accuracy between the mean and median projections depends on turning points in the economy. Dovern, Fritsche, and Slacalek (2012) have documented a cyclically sensitive cross-sectional forecast variation, a phenomenon that also holds in the SPF. This finding suggests that the number of panelists reporting extreme forecasts in a survey is cyclically sensitive. Further, because extreme projections can weigh more heavily on the mean consensus forecast than on the median, relative forecast accuracy between the mean and median could well depend on the business cycle. In future work, we plan to investigate relative forecast accuracy of the mean and median projections conditional on the business cycle, using the test proposed by Giacomini and White (2006).

¹¹ Operationally, we conduct our Diebold–Mariano tests by running the Diebold–Mariano regression given by $\varepsilon_{1,t+\tau|t}^2 - \varepsilon_{2,t+\tau|t}^2 = \mu + U_{t+\tau|t}$ where the dependent variable is the difference in the squared forecast errors, as previously defined; μ is the population difference in the MSE; and $U_{t+\tau|t}$ is the regression error.

Brief, we test whether the median projection is as accurate a consensus projection as the mean projection. Looking over many variables, alternative sample periods, different measures of realizations, and five quarterly forecast horizons, we generally find statistically insignificant differences between mean and median forecast accuracy. When we do find statistical significance, the difference in forecast accuracy is often small and the percent difference in the RMSE is usually less than 5 percent, indicating that we may continue using the median forecast as the consensus forecast.

Of particular interest is that our results suggest generally no differences between the mean and median forecasts for the unemployment rate, real GDP, and inflation. Specifically, for real GDP and unemployment, we found almost always that the mean and median forecasts were statistically indistinguishable or that the percent difference in the RMSEs was usually less than 5 percent. ^{RB}
