Abstract

We study the design of efficient intertemporal payment arrangements when the ability of agents to perform certain welfare-improving transactions is subject to random and unobservable shocks. Efficiency is achieved via a payment system that assigns balances to participants, adjusts them based on the histories of transactions, and periodically resets them through settlement. Our analysis addresses two key issues in the design of actual payment systems. First, efficient use of information requires that agents participating in transactions that do not involve monitoring frictions subsidize those that are subject to such frictions. Second, the payment system should explore the trade-off between higher liquidity costs from settlement and the need to provide intertemporal incentives. In order to counter a higher exposure to default, an increase in settlement costs implies that the volume of transactions must decrease, but also that the frequency of settlement must increase.

Keywords: Payment Systems, Subsidization across Transactions, Liquidity Costs, Default

1 Introduction

Most models of decentralized exchange abstract from the institutions that enable such exchange and, hence, from their efficient design. This is in sharp contrast to the immense volume of transactions that are facilitated through payment systems in modern economies. Lacker and Weinberg (2003) and more recently Kahn and Roberds (2006) argue, therefore, that studying payment systems, and more broadly payment economics, is essential for understanding decentralized exchange and for designing institutions that can support it efficiently. However, they also point to the lack of a concise and integrated framework that can guide policymakers in the efficient design of such a system. The challenge is twofold. On the one hand, such a framework requires a modelling of the fundamental reasons why a payment system (PS) is necessary; on the other hand, answering questions about the efficient design of such systems requires a general welfare analysis.

The goal of this paper is to address these challenges. We build a dynamic general equilibrium environment in which transactions are subject to a private information friction. To have an explicit role for transactions, we incorporate a standard search model into our framework. In the spirit of search models, the random matching shocks that agents are subject to are a tractable way of modelling random needs for liquidity. This is an important feature of actual PS in which participants are subject to random needs for making payments to one another. Moreover, the model is consistent with the fact that actual transactions are bilateral and, frequently, subject to private information. For example, within a retail PS, a consumer's ability to make a credit card payment might not be observable. Similarly, within a wholesale system, banks might have private information about the necessity of making certain payments.

We will assume that each transaction involves an agent that enjoys an instantaneous benefit and one that suffers an instantaneous cost.² In the presence of private information

¹Although our model does not involve currency, we use the framework of Kiyotaki and Wright (1989, 1993), which was developed in order to study monetary exchange.

²There are several ways to rationalize such costs and gains. In a wholesale PS, for example, a bank might

about agents' ability to produce or consume, the rules imposed by the PS must provide the right incentives for its participants to both be part of the arrangement and reveal their information truthfully. The PS in our model accomplishes this by assigning individual "balances" and by specifying rules on how these balances are updated given the participants' trading histories. Furthermore, the PS requires that balances be "settled." This implies that participants are required to periodically "reset" their balances through centralized trading in what we will model as a Walrasian market.

Our dynamic model allows us to study the use of intertemporal incentives in order to explore the participants' willingness to be part of the system and carry out transactions efficiently.³ Transactions are "linked" through the settlement stage in which participants erase obligations from their transactions by interacting through markets. This fits well with observations from actual PS, which almost always involve repeated interactions between the system and its participants, with settlement playing a key role in shaping these incentives. In Koeppl, Monnet, and Temzelides (2007), we addressed only the necessity of settlement for a PS under very special circumstances. We left aside two crucial features for studying the optimal design of PS. First, some transactions in a PS can often be monitored better than others.⁴ Second, settlement involves costs that influence the trade-off between liquidity need to incur a cost in order to make a payment while enjoying a direct benefit from receiving the payment. In the context of a retail PS, a consumer who receives a good or service enjoys an immediate benefit while the cost is borne by its supplier. To fix ideas, we will hence refer to the two agents in the transaction as the "consumer" and the "producer," respectively.

³While most of the existing literature on PS is exclusively static (see Kahn and Roberds (1998, 2001) for two prominent papers), our work is most closely related to the dynamic contracting literature (see Green (1987), and Spear and Srivastava (1987), among others). Our analysis is also related to recent work by Kocherlakota (2005), who extends the model of Mirrlees (1971) to a dynamic economy. The payment system in our model plays an analogous role to that of the tax authority in Kocherlakota (2005): it explores intertemporal incentives in order to decentralize efficient allocations under private information.

⁴For example, in some wholesale PS, banks interact mostly, but not exclusively, through a local network. Such networks, which are often run by large correspondent banks, might have detailed information about their participants. The same information, however, might not be available to the PS when a bank transacts outside its network. Similarly, in the context of retail PS, a consumer's credit card history might be readily

and incentives.

This paper attempts to answer two questions that are paramount to optimal PS design. The first concerns the efficient use of information when choosing optimal balance adjustments. In the case when some transactions can be monitored (i.e., they can be publicly observed), we demonstrate how an optimal PS must use this information to relax the incentive constraints of certain participants. More precisely, the PS will "tax" monitored transactions in order to "subsidize" the costs of providing incentives in transactions that are subject to private information. Also, we find that an optimal PS will shift the costs of providing incentives from the transaction to the settlement stage. Producers in the transaction stage are rewarded through balance increases, while consumers are penalized through balance decreases. These rewards and costs materialize when participants equalize their balances during settlement.

The second question concerns the study of how costs associated with settlement influence the trade-off between liquidity and incentives. Most actual large-value PS now involve immediate finality of settling transactions, a feature that requires the presence of liquid funds in the system. As a response to increased liquidity costs, PS often offer short-term credit facilities, at the expense of potentially increasing default risk. Optimal PS design must explore the trade-off between minimizing liquidity costs and dealing with default exposures. This trade-off has a clear counterpart in our model. As participants need an incentive to settle their obligations periodically, we find that an optimal PS must decrease the need for large payments by limiting the overall volume of transactions. At the same time, settlement increases the liquidity available to participants as it enables them to engage in future transactions. Increased liquidity, in turn, allows for a larger volume of transactions. However, a larger volume of transactions increases the incentive for participants to default. Hence, an endogenous trade-off between liquidity and default arises naturally.

available within a credit card network, but not necessarily within other networks.

⁵Here we do not phrase this discussion in terms of gross versus net settlement systems, as this refers to the finality of payments or, in other words, to the discharge of bilateral exposures from transactions. This is different from the overall amount of credit granted in a payment system, which is *independent* of finality.

We then introduce a fixed cost of settlement. We define the cost of liquidity as the ratio of the fixed cost to the volume of transactions in the PS. When participants settle more frequently, given a transactions size, the cost of liquidity increases. The cost of settlement can thus be interpreted as a cost for holding liquidity needed for settling balances with the system.⁶

We demonstrate that, somewhat surprisingly, in an optimal PS, an increase in the fixed settlement cost results in a *lower* volume of transactions. Furthermore, this is achieved not only by a decrease in the size of transactions, but also by *increasing* the frequency of settlement. Thus, while liquidity decreases, the overall costs of liquidity in the PS increase. The reason is intuitive. Increasing the fixed costs of settlement in our model also increases the incentives to default. To balance this risk, the PS then needs to improve the incentives for participants to settle. This is achieved by lowering total credit available in the system. Thus, our result stands in contrast to the existing literature, which does not consider incentive effects and simply trades off default costs versus opportunity costs of funding liquidity in the payment system.

The paper proceeds as follows. Section 2 introduces the model and discusses the concept of a PS. Sections 3 and 4 discuss optimal balance adjustments and the optimal frequency of settlement. Section 5 offers a brief conclusion and discusses some of the many possible directions for future research. The Appendix introduces a continuous-time extension of the model and contains the proofs.

⁶An analog in actual PS would be the costs of pre-funding positions in the system after end-of-period settlement. Larger positions are more costly, but they allow for a larger volume of transactions. In a broader context, one could alternatively interpret such costs as access (or operational) costs.

2 A Dynamic Model of Payments

2.1 The Environment

Time, t, is discrete and measured over the natural numbers. There is a [0,1] continuum of infinitely lived agents. The common discount factor is $\beta \in (0,1)$. We assume a periodic pattern of length n, in which n transaction stages, each consisting of exactly one bilateral meeting for every agent, are followed by a round of centralized trading (termed settlement stage) at the end of the last period. Discounting applies after each period, except between the last transaction stage and the settlement stage. We describe the transaction stage and the settlement stage in turns.

During the transaction stage, agents are randomly matched bilaterally in each period. Randomness in the transaction needs is captured by assuming that in each period, an agent can trade with the agent he is matched with as a producer or as a consumer, each with probability γ . Thus, in each period during the transaction stage, an agent is in a trade meeting with probability 2γ . Agents cannot pre-commit to produce in such meetings. With probability $(1-2\gamma)$, an agent is in a no-trade meeting. Production in the transaction stage is perfectly divisible, and the produced goods are non-storable. Producing q units implies disutility -c(q), while consumption of q units gives utility u(q) where $q \in \mathbb{R}_+$. We assume that c'(q) > 0, $c''(q) \ge 0$, $\lim_{q\to 0} c'(q) = 0$, and $\lim_{q\to \infty} c'(q) = \infty$. In addition, u'(q) > 0, $u''(q) \le 0$, $\lim_{q\to 0} u'(q) = \infty$, and $\lim_{q\to \infty} u'(q) = 0$. Thus, there exists a unique q^* such that $u'(q^*) = c'(q^*)$. The quantity q^* gives the efficient level of output in the sense that it uniquely maximizes the joint surplus created in a transaction. Since we concentrate on this quantity for most of the paper, we will simplify notation by letting u denote $u(q^*)$ and c denote $c(q^*)$.

⁷Lagos and Wright (2006) introduced similar periodic trading patterns in monetary models. The continuum assumption precludes aggregate risk. Issues related to optimal PS design in the presence of aggregate risk are of great interest, but beyond the scope of this paper.

⁸We reiterate that what is important is that each transaction involves an agent that enjoys an instantaneous benefit and an agent that suffers an instantaneous cost. In a wholesale system these costs and

The information structure during the transaction stage is as follows. Whether or not a trade meeting has occurred is always observable to the two agents in the meeting. This, together with the identities of the two agents, is also publicly observable with probability α . On the other hand, with probability $1 - \alpha$, neither the identities of the two agents nor the type of their meeting is observable by anyone outside the meeting. While the opportunity to trade is not observable in non-monitored meetings, we assume that, should they take place, production and consumption are always verifiable.

During the settlement stage, each agent can produce and consume a general non-storable good. No other good can be produced or consumed during this stage. Producing ℓ units of the general good implies disutility $-\ell$, while consuming ℓ units gives utility ℓ . Thus, trading this good does not directly increase welfare. The settlement stage is frictionless in the sense that, just as in Walrasian markets, agents interact in a centralized fashion, and there are no informational frictions.

2.2 Payment Systems

An allocation for the above environment specifies the quantity produced and consumed during bilateral transactions, as well as the production and consumption of the general good for each agent during settlement. In general, allocations may well exhibit history-dependence. In this paper we concentrate on whether efficient allocations can be decentralized through a payment system (PS). A PS keeps a record of past transactions by assigning balances to its participants. In addition, the PS instructs participants to produce or consume certain quantities in trade meetings and specifies rules for how the balances are updated given the participants' current transactions. Finally, during the settlement stage, participants trade benefits will typically be associated with costly payments of size q made by one participant to the other. The functions c and u provide a reduced-form way of capturing such costs and benefits.

⁹This information structure can be the result of the agents being divided into two symmetric networks. Each agent needs to transact within his network with probability α , and with another participant outside his network with probability $1 - \alpha$. In this interpretation, "within-network" meetings are monitored, while during "inter-network" meetings the ability to transact is private information of the trading partners.

their balances against the general good in order to achieve a particular starting balance for the next transaction stage. Agents with low balances can then increase their balances by producing, while those with high balances can reduce them by purchasing consumption of the general good. Since we model the settlement stage as a Walrasian market, the price, p, at which balances are traded, is determined by market clearing conditions. We make three additional assumptions. First, we restrict attention to allocations that are stationary and symmetric across agents.¹⁰ Second, we assume that the PS can permanently exclude from all future transactions agents that do not produce or consume the prescribed amount during monitored transactions or do not settle their balances. Finally, we rule out short-sales of balances in the Walrasian market. Later we will assume that each settlement stage involves an aggregate (average) resource cost $\delta > 0$ and study the implications of this cost for optimal settlement frequency. For simplicity, we first formulate the general framework assuming that $\delta = 0$.

Formally, the PS keeps a record of all transactions. For any agent, in any given period, t, this record is summarized by his balance, $d_t \in \mathbb{R}$. First, consider the problem of an agent in the settlement stage at time t. Let $V_t(d_t, p_t)$ denote his value function if he exits the last bilateral meeting in the transaction stage with balance d_t , given that the anticipated price in the following settlement stage is p_t . Let $E_t v_{t+1}(\hat{d}_t, \Psi_{t+1})$ denote the expected future value of an agent who exits the settlement stage with balance \hat{d}_t , given that the resulting distribution of balances is denoted by Ψ_{t+1} . The problem of the agent is then given by

$$V_t(d_t, p_t) = \max_{\ell_t, \hat{d}_t} -\ell + \beta E_t v_{t+1}(\hat{d}_t, \Psi_{t+1})$$
(1)

subject to

$$p_t \widehat{d}_t = p_t d_t + \ell_t \tag{2}$$

$$\widehat{d}_t \ge \min\{0, d_t\}. \tag{3}$$

In this problem we have imposed the constraint that agents cannot short sell their bal-

¹⁰This is without loss of generality when, as is the case in most of the paper, the full-information-first-best allocation is decentralized.

ances in the Walrasian market. Note that, given a price level p_t , V_t is linear in balances, d_t .¹¹ While it is not necessary for the results, linearity greatly simplifies our analysis.

We now turn to the problem faced by the participants during the transaction stage. In each period, agents are bilaterally matched. In non-monitored meetings, the PS receives a joint report from the agents in the match. Formally, the two agents, say, i and j, each report a number $\eta_i, \eta_j \in \{0, 1\}$. The agents' identities become known to the system if and only if $\eta_i \eta_j = 1$. If either agent chooses 0, so that $\eta_i \eta_j = 0$, the agents' identities are not revealed, and the PS instructs them to exchange nothing. If both choose 1, they identify themselves to the PS as being in a trade meeting. The potential producer is then instructed to produce $q_t(d_t, d'_t, \Psi_t)$ for the potential consumer. Note that q_t can depend on both participants' balances as well as on the overall distribution of balances. In a monitored meeting, no such reporting needs to occur, since in that case the type of the meeting is observable to the PS. Hence, the PS instructs people directly to trade a quantity $\bar{q}_t(d_t, d'_t, \Psi_t)$. Again, this quantity can depend on the balances of both participants as well as on the overall distribution.

Upon observing the reports and the production and consumption by every agent, the PS adjusts balances. An adjustment, $X_t(d_t, d'_t, \Psi_t) \in \mathbb{R}$, is thus made to an agent's current balance, conditional on his current trading history, as summarized by his current balance. Recall that an agent can be in a consumption, a production, or a no-trade meeting. In addition, the meeting is either monitored or non-monitored. This results in six possible adjustments for each transaction round; i.e., $X_t \in \{L_t, K_t, B_t, \bar{L}_t, \bar{K}_t, \bar{B}_t\}$. More precisely, $L_t(K_t)$ is the adjustment for a participant who consumes (produces), while B_t is the adjustment for a participant who does not transact in a non-monitored meeting. The variables \bar{L}_t , \bar{K}_t , and \bar{B}_t are defined analogously for monitored meetings. Balances are represented by real numbers not restricted in sign, while production of goods during trade meetings is restricted to be positive.¹² Agents may decide to leave the PS at any point. In that case, we assume

¹¹This follows from an argument similar to that in Lagos and Wright (2006).

¹²To further clarify the information-related problem, the difficulty is that whether or not a trade meeting has taken place is not always observable to the PS. Thus, any arrangement must rely on reports by the agents about the type of meeting that has taken place. The transaction protocol we have formulated for

that they cannot be re-admitted, and that they receive a permanent future payoff that is normalized to zero. We can now formally define a PS.¹³

Definition 1. A payment system is an array

$$S_t(d_t, d'_t, \Psi_t) = \{L_t, K_t, B_t, q_t, \bar{L}_t, \bar{K}_t, \bar{B}_t, \bar{q}_t\}, \text{ for all } t.$$

We restrict attention to PS that are *incentive feasible*. We term a PS incentive feasible if (i) all agents have an incentive to participate in each transaction, as well as in the settlement stage, (ii) all agents in non-monitored transactions truthfully reveal the type of meeting they are in, and (iii) the market clears in each settlement stage. The last requirement implies that in each t that corresponds to a settlement stage,

$$\int_{d_t} (\widehat{d}_t - d_t) d\Psi_t = 0. \tag{4}$$

This, in turn, immediately implies that $\int_{d_t} l_t d\Psi_t = 0$. To formulate incentive compatibility (IC) and participation constraints (PC), we first describe the value functions of participants during the transaction stage. Recall that there are n bilateral meetings (one in each period) between settlement stages. To ease notation, we denote the current-period immediate return in period t by $f(X_t)$, where $X_t \in \{L_t, K_t, B_t, \bar{L}_t, \bar{K}_t, \bar{B}_t\}$. Thus, $f(L_t) = u(q_t)$, $f(K_t) = c(q_t)$, and $f(B_t) = 0$. The adjustments for monitored meetings, \bar{L}_t , \bar{K}_t , and \bar{B}_t , are defined similarly. If the last settlement stage occurred in period t, the value function during each round $s, s = 1, \ldots, n-1$, of the current transaction stage is given by

$$E_{t+s-1}[v_{t+s}(d_{t+s-1}, \Psi_{t+s-1})]$$

$$= \int_{d'_{t+s}} E[f(X_{t+s}) + \beta E_{t+s}[v_{t+s+1}(d_{t+s-1} + X_{t+s}, \Psi_{t+s})]]d\Psi_{t+s-1},$$
(5)

non-monitored meetings has the following interpretation. Each participant in the system has access to both a "card" and a "card-reading machine." Agents can choose to identify themselves to the PS by having their card read by their partner's machine ($\eta_i = \eta_j = 1$). In that case, the system becomes aware that the two agents are in a trading meeting. The balances of both parties are then updated given their reports and the production/consumption that has taken place.

¹³Strictly speaking, a PS must also be a function of whether an agent chooses to participate in the system or not. For simplicity, we leave this indicator variable out of the formal definition of a PS.

where E denotes the expectation over the type of meeting the agent will be in during the current period.¹⁴ For the last period of the transaction stage, t + n, we have

$$E_{t+n-1}[v_{t+n}(d_{t+n-1}, \Psi_{t+n-1})] = \int_{d'_{t+n}} E[f(X_{t+n}) + V(d_{t+n-1} + \bar{X}_{t+n}, p_{t+n})] d\Psi_{t+n-1}.$$
 (6)

Since consumption and production are verifiable, agents can only misreport during a non-monitored transaction by claiming that they are in a no-trade meeting. Assuming that the last settlement stage occurred at time t, allocations are IC during each round s, $s = 1, \ldots, n-1$, of the current transaction stage if in all non-monitored transactions we have

$$f(X_{t+s}) + \beta E_{t+s}[v_{t+s+1}(d_{t+s-1} + X_{t+s}, \Psi_{t+s})] \ge f(B_{t+s}) + \beta E_{t+s}[v_{t+s+1}(d_{t+s-1} + B_{t+s}, \Psi_{t+s})],$$

$$(7)$$

where $X_{t+s} \in \{K_{t+s}, L_{t+s}, B_{t+s}\}$. Similarly, for s = n, IC requires that for all X_{t+n} ,

$$f(X_{t+n}) + V(d_{t+n-1} + X_{t+n}, p_{t+n}) \ge f(B_{t+n}) + V(d_{t+n-1} + B_{t+n}, p_{t+n}).$$
(8)

Finally, PC require that agents have an incentive to remain in the PS during both the transaction and the settlement stages. Thus, if the last settlement stage occurred at t, we require

$$f(X_{t+s}) + \beta E_{t+s}[v_{t+s+1}(d_{t+s-1} + X_{t+s}, \Psi_{t+s})] \ge 0, \tag{9}$$

for all X_{t+s} , and all $s=1,\ldots,n-1$. Finally, for s=n we require

$$f(X_{t+n}) + V(d_{t+n-1} + X_{t+n}, p_{t+n}) \ge 0, (10)$$

for all X_{t+n} . The absence of short-sales implies that settlement involves a positive expected lifetime payoff, independent of any balance adjustments. Otherwise, agents would default on their obligations. Formally,

$$V(d_{t+n-1} + X_{t+n}, p_{t+n}) \ge 0. (11)$$

¹⁴For example, $\alpha \gamma$ gives the probability that the agent is engaged in a monitored production meeting. To ease notation, we have suppressed the dependence of the PS on $(d_{t+s}, d'_{t+s}, \Psi_{t+s})$.

In most of the paper, we will concentrate on implementing the full-information-first-best allocation, in which the efficient transaction level q^* is exchanged in *all* trade meetings, both monitored and non-monitored.¹⁵ We have the following.

Definition 2. A PS is optimal if it is incentive feasible and if it decentralizes the efficient level of production, q^* , in all trade meetings.

To conclude this section, it is useful to specify two particular types of PS that we will use extensively in what follows. A PS is *simple* if balance adjustments do not depend on the agents' current balances. Hence, a simple PS is not a function of the agent's history during the transaction stage. A PS is *simple* and *repeated* (SRPS) if, in addition, it satisfies

$$X_{t+s} = \frac{X_{t+n}}{\beta^{n-s}}, \text{ and}$$
 (12)

$$X_{t+kn} = X, (13)$$

where $X \in \{L, K, B, \bar{L}, \bar{K}, \bar{B}\}$, s = 1, ..., n, and $k \in \mathbb{N}$. In the above expressions, t represents the date of a settlement round. In words, adjusting for discounting, a repeated PS imposes the same balance adjustments in each period of the transaction cycle. To ease notation, we will drop the time index whenever possible. SRPS are convenient since the linearity of V implies that in any optimal SRPS, the incentive constraints for all s, s = 1, ..., n-1 are fulfilled whenever those for s = n hold. In what follows, we restrict attention to SRPS.

3 Efficient Use of Information

In the previous section we described an environment in which certain transactions are subject to a private information problem, and we introduced a payment system as a way of decentralizing incentive feasible allocations. In this section we use this setup to analyze some of the properties of optimal PS. We pay particular attention to how the PS can use monitored

¹⁵Linear utility in the settlement stage implies that the utility from consuming any amount of the general good equals the disutility to the producer. Hence, the efficient amount of the general good is indeterminate.

transactions in order to alleviate the incentive problem in non-monitored ones. To this end, we will first take the length of the transaction stage, n, as given, and assume that there are no settlement costs ($\delta = 0$). In the next section we study the issue of optimal settlement frequency when $\delta > 0$.

3.1 Perfect Monitoring

It is instructive to first discuss the case in which all transactions are perfectly monitored; i.e., $\alpha=1$. This special case is convenient as it involves no IC constraints. Thus, incentive feasible allocations need to satisfy only market clearing in the settlement stage and, of course, the PC. We will consider two optimal PS for this environment. First, suppose that the PS sets all balance adjustments permanently equal to zero and imposes a "gift-giving" game in which agents are induced to produce in all trade meetings under the threat of permanent exclusion in the case of a deviation. Since this PS does not rely on any balance adjustments, there is never a need to trade balances in the settlement stage. Furthermore, agents have an incentive to participate if and only if

$$\frac{\beta}{1-\beta}\gamma(u-c) \ge c,\tag{14}$$

or if the future expected discounted utility from staying in the PS is greater than the current cost of producing the efficient quantity, c. Provided that the above participation constraint holds, this PS is optimal.

Second, consider an alternative PS that uses balance adjustments in order to shift all costs related to incentive provision to the settlement stage. Denote the minimum balance adjustment in any given period by $X_t^{\min} = \min\{\bar{K}_t, \bar{L}_t, \bar{B}_t\}$ and normalize the required starting balance after the settlement stage in period t to $\hat{d}_t = 0$. Agents that do not leave the settlement stage with $\hat{d}_t = 0$, as well as those that do not exchange q^* in a trade meeting, are permanently excluded from the PS. Hence, the distribution of balances, Ψ_t , at the end

¹⁶This implies that the minimum adjustment will be negative, while agents that produce are rewarded with a positive adjustment.

of each settlement stage is degenerate, for all t. The only potentially binding PC are then given by

$$V(\widehat{d}_t + \sum_{s=1}^n X_{t+s}^{\min}, p_{t+n}) \ge 0, \tag{15}$$

and

$$f(X_{t+n}) + V(\widehat{d}_t + \sum_{s=1}^{n-1} X_{t+s}^{\min} + X_{t+n}, p_{t+n}) \ge 0.$$
 (16)

The first constraint implies that an agent chooses to settle and, thus, remains in the PS even under the worst possible history of adjustments. The second constraint is the PC for agents in the last transaction round, conditional on having had the worst balance adjustment until this round. Such agents still need an incentive to carry out the transaction as they can always avoid the cost $f(X_{t+n})$ by leaving the PS prior to the settlement stage. Finally, the PS must satisfy the market clearing condition during settlement (4) with $\hat{d}_{t+n} = 0$; i.e.,

$$\gamma p_t \sum_{s=1}^n \bar{K}_{t+s} + \gamma p_t \sum_{s=1}^n \bar{L}_{t+s} + (1 - 2\gamma) p_t \sum_{s=1}^n \bar{B}_{t+s} = 0.$$
 (17)

Since we restrict attention to PS that are simple and repeated, we can use (12) and (13) to simplify the above market clearing condition to

$$\gamma p_t \bar{K} + \gamma p_t \bar{L} + (1 - 2\gamma) p_t \bar{B} = 0. \tag{18}$$

Let p denote the (constant) equilibrium price in the settlement round. We then have the following.

Proposition 3. Suppose that $\alpha = 1$. If $\frac{\beta}{1-\beta}\gamma(u-c) \geq c$, the PS with no balance adjustments $(\bar{K}_t = \bar{L}_t = \bar{B}_t = 0, \text{ for all } t)$ is optimal. If $\beta^n u \geq c$, the simple repeated PS with balance adjustments $p\bar{K} = p\bar{L} + c = p\bar{B} + c$ is optimal.

The proof is in the Appendix. Notice that the condition that $\beta^n u \geq c$ requires that settlement be sufficiently frequent. Thus, if n is large, the second PS is no longer optimal, since it is not incentive feasible. It is easy to check that as long as

$$\gamma \ge \frac{\beta^n}{1 - \beta^n} \frac{(1 - \beta)}{\beta},\tag{19}$$

the first PS is optimal for the widest set of parameter values. In other words, provided that this inequality holds, if an optimal PS exists, the first PS is also optimal. Of course, there exist parameters for which both of the above PS are optimal. The main difference between the two is that the first PS does not employ settlement, while the second one collects all costs from incentive provision during the transaction stage and periodically resets the participants' balances through settlement.

3.2 Cross-Subsidizing Transactions

Before we analyze the possibility of cross-subsidization, it is useful to first consider the other extreme case in which there are no monitored transactions ($\alpha = 0$). In this case, the PS relies on reports by participants about whether or not they are in a trade meeting. By the linearity of V in d, the relevant IC in any period s, $s = 1, \ldots, n$, during the transaction stage are given by

$$-c(q_{t+s}) + \beta^{n-s} p_{t+n} K_{t+s} \ge \beta^{n-s} p_{t+n} B_{t+s}$$
, and (20)

$$u(q_{t+s}) + \beta^{n-s} p_{t+n} L_{t+s} \ge \beta^{n-s} p_{t+n} B_{t+s}. \tag{21}$$

In this case, the SRPS that uses the balance adjustments described in the second part of Proposition 3 is optimal if and only if $\beta^n u \geq c$. Of course, as long as $\beta^n u \geq c$, this PS also remains optimal for any $\alpha \in [0,1]$. Indeed, even if $\alpha > 0$, the PS can always treat all transactions as if they are non-monitored and make balance adjustments as in Proposition 3.

The above PS, however, does not exploit the fact that as long as $\alpha > 0$, some transactions are monitored. Hence, the question arises whether an optimal PS exists if $\beta^n u < c$ that explores this information. The following Proposition asserts that this is indeed possible through a PS that "taxes" some of the surplus created in monitored transactions in order to relax the incentive constraints by "subsidizing" non-monitored transactions.

Proposition 4. Assume that $\beta^n u < c$. There exists an optimal simple repeated PS if and

only if

$$\frac{\beta}{1-\beta}\gamma(u-c) - c \ge (1-\alpha)\gamma\left(\frac{\beta}{\beta^n}\frac{1-\beta^n}{1-\beta}\right)c. \tag{22}$$

For any parameter values satisfying the above inequality, the PS with balance adjustments $p\bar{K} = p\bar{L} = p\bar{B} = pL = -(1-\alpha)\gamma c$ and pK = pB + c is optimal.

The intuition behind this result is straightforward. First, recall that cross-subsidization is useful only when $\beta^n u < c$ (otherwise we already know that an optimal PS exists). This, together with (22), implies that (19) holds. Thus, without loss of generality, we employ the PS that uses a gift-giving game during monitored transactions. The left-hand side of inequality (22) is the maximum total tax revenue that an optimal PS can extract when it employs a gift-giving game. The right-hand side gives the total subsidy required in a settlement stage for the incentive constraints to be satisfied for non-monitored producers. In other words, the above PS imposes a uniform lump-sum tax on all participants and then uses the proceeds to make the incentive constraints for non-monitored producers hold. Such a PS is optimal as long as the available taxes are high enough to subsidize the cost of providing incentives to non-monitored producers.

We remark that the restriction to SRPS likely involves some loss of generality, since such a PS cannot extract all possible surplus. Indeed, a PS that would be a function of the entire history of all transactions since the last settlement stage could potentially redistribute surplus more efficiently. Finally, note that since we assume that $\beta^n u < c$, condition (22) cannot be met if $\alpha = 0$, in which case there are no monitored transactions to finance the incentive subsidy.

It is worth pointing out that, as the above analysis suggests, balances in our model are distinct from currency in at least one important way. When two agents transact using currency, the amount of money that the seller receives is equal to the amount that the buyer offers. Here, however, in order for non-monitored transactions to be subsidized, it is necessary that *both* the buyer and the seller in monitored transactions receive a negative balance adjustment. The ability to implement such a policy, which is analogous to a transaction-specific tax or subsidy, distinguishes the PS in our model from a monetary authority imposing

an inflation tax.

4 Liquidity and Incentives

Settlement resets the balances of participants. Hence, it provides liquidity in the sense that agents have an incentive to engage in a new round of transactions. Our model naturally captures the fact that infrequent settlement increases the potential for default. However, the analysis has abstracted so far from costs directly associated with settlement. Instead, we have assumed that the length of the transaction stage is exogenously given. We now turn to the question of how to optimally balance such costs against the higher default exposure associated with less frequent settlement.

For the remainder of the paper, we assume that there is a fixed cost, $\delta > 0$, that is incurred in each period in which settlement takes place. The existence of such a cost is important if one wants to study the frequency of settlement as a policy variable chosen by the PS. Indeed, as pointed out earlier, such a cost links the frequency of settlement to higher levels of liquidity in the PS. In the absence of such costs, our model implies that an optimal PS will have settlement occurring after each transaction; i.e., n = 1.

To streamline the analysis, we now abstract from questions related to cross-subsidization of transactions and study the benchmark case in which there is no monitoring ($\alpha = 0$). We will also assume that δ is small enough, so that settlement must periodically occur as part of an optimal PS. Finally, we assume that δ is generated through production of the general good during the settlement stage.

Our first goal is to characterize the values of n for which an optimal PS exists in the presence of the fixed settlement cost δ . We then show that the particular way that this cost is divided across participants is not important. The reason is that what matters for incentives is the *overall* balance adjustments, which are inclusive of these costs. Finally, we study the trade-off between transaction size and settlement frequency.

4.1 Settlement Costs

Building on our earlier findings, we consider a PS that sets balance adjustments such that pK = pB + c = pL + c. This satisfies all IC and PC (see equations (20) and (21)). The PS must now also recover the cost δ . Hence, market clearing during the settlement stage is now given by

$$\gamma \sum_{s=1}^{n} K_{t+s} + \gamma \sum_{s=1}^{n} L_{t+s} + (1 - \gamma) \sum_{s=1}^{n} B_{t+s} = -\frac{\delta}{p_{t+n}}.$$
 (23)

Assuming that participants share the settlement costs equally,¹⁷ the value function, V, of an agent prior to entering the settlement stage is now given by

$$V(d_t, p_t) = d_t p_t + \frac{\beta}{1 - \beta} \gamma(u - c) + \delta \left(\frac{\beta^n}{1 - \beta^n}\right).$$
 (24)

We have again assumed, without loss of generality, that the PS sets the desired balance at the end of the settlement stage to $\hat{d}_t = 0$. Like before, the first two terms of the value function give the value of the agent's current balances and the future expected utility from participating in the PS, respectively. The last term gives the present value of all future settlement costs.¹⁸

Like before, it is sufficient to check that the PC under the worst possible balance adjustments holds during the last period of the transaction stage. For the above PS, this constraint is given by

$$pL\left(\frac{\beta}{1-\beta}\right)\left(\frac{1-\beta^n}{\beta^n}\right) \ge -\frac{\beta}{1-\beta}\gamma(u-c) + \delta\left(\frac{\beta^n}{1-\beta^n}\right). \tag{25}$$

One can use the market clearing condition to solve for the implied adjustment for consumers, L, which is given by

$$pL = -\delta \left(\frac{1-\beta}{\beta}\right) \left(\frac{\beta^n}{1-\beta^n}\right) - \gamma c. \tag{26}$$

Substituting this into the PC, we obtain

$$\beta^n u - c \ge \frac{\delta}{\gamma} \left(\frac{1 - \beta}{\beta} \right) \left(\frac{\beta^n}{1 - \beta^n} \right). \tag{27}$$

¹⁷As we show in the next section, this is without loss of generality.

¹⁸The current settlement cost is contained in the agent's balance, d_t .

Hence, any n satisfying this condition allows the above PS to decentralize the efficient transaction level, q^* . We then have the following.

Proposition 5. Assume that $\alpha = 0$. There exists an optimal simple repeated PS if and only if

$$\beta^n u - c \ge \frac{\delta}{\gamma} \left(\frac{1 - \beta}{\beta} \right) \left(\frac{\beta^n}{1 - \beta^n} \right). \tag{28}$$

For any parameter values satisfying the above inequality, the PS with balance adjustments pK = pB + c = pL + c is optimal. The optimal settlement frequency, n^* , is the maximum n for which this condition holds.

Conditional on decentralizing an efficient allocation, an optimal PS should minimize the incurred costs from settlement. In other words, the PS must choose the longest length of a transaction stage that is compatible with optimality, given the costs δ as expressed by (27). Such an n exists as long as $\delta \leq \gamma(\beta u - c)$. Note also that, if n is large enough, we have that

$$\beta^n u < c. \tag{29}$$

Thus, if settlement is sufficiently infrequent (n is sufficiently large), the PC of an agent that consumed n times in a row will be violated. In other words, there exists a maximum n such that constraint (27) is satisfied.

4.2 Financing Settlement Costs

Throughout, we are assuming that the PS is self-financed. This implies that the fixed cost, δ , associated with its operation must be entirely financed by PS participants. In our analysis so far, we assumed that δ is shared equally by all participants. Here we study the division of δ across participants and show that the distribution of costs does not matter for the optimality of the PS.

For simplicity, we set n=1. Denote the value of the cost paid by each producer by δ_K . Consumers and non-traders pay δ_L and δ_B , respectively. Clearly, since we assume that the PS is self-financed, we have

$$\gamma \delta_K + \gamma \delta_L + (1 - 2\gamma) \,\delta_B = \delta. \tag{30}$$

The IC (20) and (21) are then given by

$$pK - \delta_K - c \ge pB - \delta_B$$
, and (31)

$$u + pL - \delta_L \ge pB - \delta_B. \tag{32}$$

Assuming, as before, that $\hat{d}_t = 0$, and since the expected settlement cost in any future period is given by δ , the PC (16) is given by

$$f(X) + pX - \delta_X \ge -\frac{\beta}{1-\beta} \left[\gamma(u-c) - \delta \right]. \tag{33}$$

This PC implies that if an optimal PS exists, one can always construct an optimal PS by setting balances such that $pK - \delta_K - c = pB - \delta_B = pL - \delta_L$. Hence, we have the following.

Proposition 6. Suppose that an optimal simple repeated PS exists. Then, there exists an optimal PS in which settlement costs are shared equally across all agents; i.e., $\delta_L = \delta_B = \delta_K = \delta$.

The intuition for this result is straightforward. The right-hand side in (33) gives the value to a participant who stays in the PS after settlement. This value is independent of his history of past transactions. An optimal PS can always set balance adjustments so as to make all PC exactly binding.¹⁹ In that case, when $\delta = \delta_K = \delta_B = \delta_L = 0$, the PS sets pK = pB + c = pL + c. If δ increases, such a PS would increase the costs to all agents so as to keep the incentives to participate the same across all agents.

The above argument continues to hold even if n > 1, as long as $\alpha = 0$. Of course, other cost allocations can also be consistent with an optimal PS. However, it is worth mentioning that when $\alpha > 0$, it is the PC for agents that have consumed n-times in a row that will bind first. In that case, any optimal PS will levy a higher share of the settlement costs on non-consumers; i.e., $\delta_L = \delta_B < \delta_K$. The rationale for this policy prescription is different from the standard argument that competitive forces drive the allocation of PS costs. Rather,

¹⁹This is not a necessary feature of optimal PS. However, if an optimal PS exists, one can always construct another optimal PS that satisfies this property. It is this property that characterizes PS that are optimal for the widest range of parameter values.

the above argument suggests that in order to reduce their incentive to default during the settlement stage, it is the agents that are most constrained who must pay the lowest share of the costs.

4.3 Settlement Frequency and Transaction Size

It is widely recognized among PS practitioners that actual PS involve certain liquidity costs for participants who hold reserves in the system. Hence, actual PS often make provisions, such as offering short-term credit facilities, in order to economize on such costs. Offering credit, however, is not without its own costs, since it might increase default risk in the system. In this section, we study this trade-off in the context of our model.

So far in our analysis we have termed a PS optimal if it decentralizes the efficient output level, q^* , in all transactions. In the presence of settlement costs, however, an optimal PS might need to explore the trade-off between reducing the size of transactions versus lengthening the transaction stage. We now turn to the more general problem of determining *jointly* the efficient settlement frequency and the efficient transaction size.

We assume that $\delta \leq \gamma(\beta u - c)$. Settlement costs must be small enough, so that it is optimal for settlement to occur eventually. Based on our earlier findings, since $\alpha = 0$, we assume that the fixed cost δ is shared equally across all participants and is covered by production of the general good in the settlement stage. In the Appendix we use a continuous-time formulation of our model in order to set up the joint choice of settlement frequency and transaction size by the PS as a planning problem. In order for the constraint set for this problem to be convex, it is sufficient that the cost function c(q) is log-convex. Under these assumptions, we derive the following.

Proposition 7. Assume that c(q) is log-convex. Any optimal simple PS implies that $q_t = \hat{q} < q^*$, for all t. Furthermore, as δ increases, the optimal transaction size, \hat{q} , as well as the optimal length of the settlement cycle, \hat{T} , decreases.

The first part of the Proposition confirms our intuition. Proposition 5 already established that (given that q^* can be decentralized) the PS must optimally reduce settlement frequency

as much as possible in order to economize on settlement costs. The above Proposition asserts that it is also optimal to economize further on settlement costs by reducing the intensive margin; i.e., the transaction size, below its first-best level.²⁰ This is equivalent to reducing participants' exposures prior to the settlement stage, by imposing a tighter *cap* on the total amount of goods produced during bilateral transactions.

The second part of the Proposition is somewhat more surprising. It asserts that as a response to an increase in settlement costs, an optimal PS must adjust both \hat{q} and \hat{T} in the same direction. In other words, an optimal PS must reduce the volume of balance adjustments that need to be settled in two complementary ways: by shortening the length of the transaction stage, and by reducing the transaction size. The explanation for this is as follows. The binding constraint on the PS is the PC of an agent that has consumed the most during the transaction stage and, as a result, has to settle a large negative balance. An increase in δ makes it more likely that this agent's participation constraint will be violated. Hence, in order to avoid default, the PS must decrease the potential exposure of this agent by reducing his negative balance adjustments. This involves reducing both the quantity produced as well as the time between settlement periods.

5 Conclusion

One of the features of the economy that Walrasian models abstract from concerns the institutions through which payments for goods and services take place: the payment system. This results in the need for a framework that can guide policymakers in the efficient design of such systems. In this paper we proposed such a framework using mechanism design. We then asked under what conditions a PS can decentralize the efficient volume of intertemporal transactions in the presence of private information. We studied this question in a dynamic model in which the ability of agents to perform at least some welfare-improving transactions is subject to random and unobservable shocks. In particular, we examined the interplay

²⁰One can show that an optimal PS involves a constant level of production across transactions.

between monitored and non-monitored transactions. In general, the optimal PS will tax the first type of transactions in order to subsidize incentive provision for the latter type. We also discussed key issues for PS design related to optimal settlement frequency and cost recovery.

Our framework is certainly not limited to these questions and can be used to further investigate several other issues related to payments. One open question is whether more complicated payment systems than the ones considered here could decentralize efficient outcomes under less restrictive conditions. For the no-monitoring case ($\alpha = 0$), restricting attention to simple, repeated payment systems is without loss of generality. Owing to linearity in the settlement round, whenever the IC in the last period of the transaction stage hold as equalities under such a PS, all other IC in earlier rounds also hold.

When some transactions are monitored, a PS that is simple but not repeated still cannot improve on SRPS. Under any simple PS, only the total adjustments accumulated for the next settlement stage matter. Thus, a SRPS can decentralize a constant production level in all transactions that lead to at least as high total adjustments as any other simple PS. However, a PS where balance adjustments are history-dependent within a transaction cycle can likely improve on a SRPS. Hence, we would expect more conditional balance adjustments in PS with better information about participants' transactions.

We believe that our basic model can be used to address a variety of policy questions. Actual PS, for example, differ substantially on their policies regarding the financing of operational costs. While we associate δ with settlement costs here, our analysis applies to other costs associated with the operation of a PS. One example is credit card fees in retail PS.²¹ There is an ongoing debate about whether consumers or stores should be responsible for such fees. Another example is cost recovery in wholesale PS involving banks. The discussion there involves whether the "payee" or the "payer" should pay, as well as whether the fees should be fixed or volume-based.

Finally, an important debate concerns the public versus private provision of payment services. Given that our framework deals with dynamic incentives, we could investigate the

²¹Monnet and Roberds (2007) offer a careful analysis of this issue using our framework.

time consistency of various payment system policies, since optimal dynamic schemes might require some commitment. The existence of different competing payment networks and of tiered structures in PS, as well as the extension of the model to incorporate aggregate risk, outlines a whole range of interesting issues that our framework can potentially address.²²

6 Appendix

Proof of Proposition 3

For the first part of the proof, note that zero balance adjustments imply that there is no trade in the settlement stage. It can then be easily verified that when $q_t = q^*$, for all t, the PC for consumers, producers, and non-traders are the same for every period. The PC for producers is fulfilled if and only if equation (14) holds.

For the second part of the proof, we first show that PC (15) and (16) imply that all other PC are also satisfied. First, note that the value function $V(d_t, p_t)$ is linear in p_t and given by

$$V(d_t, p_t) = \frac{\beta}{1 - \beta} (u - c) + p_t (d_t - \hat{d_t}).$$
 (34)

²²Bech and Garratt (2006) investigate some related issues in a model that explicitly takes into account the network topology of payments.

Having normalized $\hat{d}_t = 0$ for all t, the PC at t + n - 1 gives

$$\begin{split} &f(X_{t+n-1}) + \beta E_{t+n-1}[v_{t+n}(d_{t+n-2} + X_{t+n-1}, \Psi_{t+n-1})] \geq \\ &f(X_{t+n-1}) + \beta E_{t+n-1}[v_{t+n}(\sum_{s=1}^{n-2} X_{t+s}^{\min} + X_{t+n-1}, \Psi_{t+n-1})] = \\ &f(X_{t+n-1}) + \beta \left[\gamma(u-c) + E_{t+n-1}[V(\sum_{s=1}^{n-2} X_{t+s}^{\min} + X_{t+n-1} + X_{t+n}, p_{t+n})] \right] = \\ &f(X_{t+n-1}) + \beta \left[\frac{1}{1-\beta} \gamma(u-c) + p_{t+n} \left(\sum_{s=1}^{n-2} X_{t+s}^{\min} + X_{t+n-1} \right) + p_{t+n} E[X_{t+n}] \right] = \\ &f(X_{t+n-1}) + \beta p_t X_{t+n-1} + \frac{\beta}{1-\beta} \gamma(u-c) + \beta p_{t+n} \left(\sum_{s=1}^{n-2} X_{t+s}^{\min} \right) + \beta p_{t+n} E[X_{t+n}] = \\ &f(X_{t+n}) + p_{t+n} X_{t+n} + \frac{\beta}{1-\beta} \gamma(u-c) + p_{t+n} \left(\sum_{s=2}^{n-1} X_{t+s}^{\min} \right) + \beta p_{t+n} E[X_{t+n}] \geq \\ &f(X_{t+n}) + p_{t+n} X_{t+n} + \frac{\beta}{1-\beta} \gamma(u-c) + p_{t+n} \left(\sum_{s=1}^{n-1} X_{t+s}^{\min} \right) = \\ &f(X_{t+n}) + V(\sum_{s=1}^{n-1} X_{t+s}^{\min} + X_{t+n}, p_{t+n}), \end{split}$$

which is just the PC for adjustment X in the last transaction round. The last inequality follows since $X^{\min} \leq 0$, and market clearing implies $E[X_{t+n}] = 0$. Hence, the PC at t+n-1 hold provided that they hold for t+n. By induction, it follows that they also hold for any t+s, $s=1,\ldots,n-2$.

Next, suppose that $\beta^n u \geq c$, and let $p_t \bar{K} = p_t \bar{L} + c = p_t \bar{B} + c$. Market clearing implies that $p_t \bar{K} = (1 - \gamma)c$. It then follows that both PC (15) and (16) are satisfied. The PS is thus incentive feasible. Since it decentralizes q^* , it is also optimal.

Proof of Proposition 4

First, note that condition (22) is equivalent to

$$\frac{c}{\gamma}(1-\beta^n)\left[\alpha\gamma - \frac{\beta^n}{(1-\beta^n)}\frac{1-\beta}{\beta}\right] \ge c - \beta^n u. \tag{35}$$

Define a PS as in the statement of the Proposition. It is clear that $K \neq X_{\min}$. In addition, all IC are fulfilled, and the PC for producers holds, since $pK \geq pB + c$. Market clearing requires that

$$\alpha p\bar{K} + (1 - \alpha)(pB + \gamma c) = 0, \tag{36}$$

or that

$$p\bar{K} = -(1 - \alpha)\gamma c. \tag{37}$$

The necessary and sufficient condition for the PS to decentralize the efficient allocation in the transaction stage is, thus, given by

$$p\bar{K}\left(1 + \frac{1}{\beta} + \dots + \frac{1}{\beta^{n-1}}\right) - c \ge -\frac{\beta}{1-\beta}\gamma(u-c). \tag{38}$$

All other PC hold if this PC involving the worst balance adjustment is fulfilled. Hence, we obtain a single condition in terms of parameters, which is given by

$$(1-\alpha)\gamma c \frac{\beta}{1-\beta} \frac{1-\beta^n}{\beta^n} - c \ge -\frac{\beta}{1-\beta}\gamma(u-c). \tag{39}$$

Rewriting this expression we obtain

$$\beta^n u \ge c + c\beta^n \frac{1 - \beta}{\beta} \frac{1}{\gamma} - \alpha c (1 - \beta^n), \tag{40}$$

or

$$\frac{c}{\gamma}(1-\beta^n)\left[\alpha\gamma - \frac{\beta^n}{(1-\beta^n)}\frac{1-\beta}{\beta}\right] \ge c - \beta^n u. \tag{41}$$

This is condition (35).

For the converse, consider again the PS specified in the statement of the Proposition. Under this PS, only the PC for monitored producers is binding. Suppose that one increases \bar{K} by any amount $\Delta > 0$, and, at the same time, lowers all other balance adjustments by $-\frac{\alpha\gamma}{1-\alpha\gamma}\Delta$, so as to satisfy the market clearing condition. This relaxes the constraint (38) if and only if

$$\alpha \gamma < \frac{\beta^n}{\beta} \frac{1 - \beta}{1 - \beta^n}.\tag{42}$$

First, suppose that this condition is satisfied. The PS can then set pK = pB + c, $p\bar{K} = p\bar{L} = p\bar{B} = pL$, and $p\bar{K}$ such that

$$pB\frac{\beta}{\beta^n}\frac{1-\beta^n}{1-\beta} = -\frac{\beta}{1-\beta}\gamma(u-c), \text{ and}$$
 (43)

$$\alpha \gamma p \bar{K} + (1 - \alpha) \gamma c + (1 - \alpha \gamma) p B = 0. \tag{44}$$

This PS is optimal for the widest possible range of parameter values. Since $B=X_{\min}$, in order to satisfy all PC, it must be the case that $p\bar{K}-c\geq pB$, or,

$$\frac{\beta^n}{1-\beta^n}\gamma(u-c) \ge \gamma c. \tag{45}$$

But this implies that $\beta^n u \geq c$, a contradiction. Hence, it must be the case that $\alpha \gamma > \frac{\beta^n}{\beta} \frac{1-\beta}{1-\beta^n}$. Suppose now that there exists an optimal PS while condition (35) is not satisfied. We have just shown that in that case the PS with $p\bar{K} = p\bar{L} = p\bar{B} = pL = -(1-\alpha)\gamma c$, and pK = pB + c is optimal for the widest possible range of parameters. But then, as condition (35) is violated, the PC for non-monitored producers, equation (38), cannot be satisfied, a contradiction.

Proof of Proposition 7

In order to demonstrate Proposition 7, we find it convenient to use differential calculus. To this end, we develop a continuous-time version of the model. We assume that consumption and production opportunities follow a Poisson process with arrival rate γ . The (continuous) rate of time preference is now denoted by ρ . The fixed cost, δ , is incurred whenever the transaction process stops and settlement occurs. This occurs after a deterministic interval of length T. As before, we denote balance adjustments by (K(t), L(t), B(t)). All other assumptions remain the same as in the text.

We let the random time before the next arrival of a trading opportunity be denoted by τ . In that case, τ has a distribution function given by

$$F(t) = \Pr(\tau \le t) = 1 - \Pr(\tau > t) = 1 - e^{-\gamma t}.$$
 (46)

Hence, the time until the next arrival of a trading opportunity is an exponentially distributed random variable with distribution function $F(t) = 1 - e^{-\gamma t}$.

In order to determine, for any given q, the expected future payoff for an agent at the end of the settlement stage, we first consider a PS that employs a gift-giving game as described in the main body of the paper. Denote this expected utility by V_0 . It is straightforward to show that an optimal PS involves a constant level of transactions. First, assume that there are no settlement costs. Since both consumption and production opportunities are independent, arrive at rate γ , and have the same continuation value, we have

$$V_{0} = \int_{0}^{\infty} e^{-\rho t} (u(q) - c(q) + V_{0}) d(1 - e^{-\gamma t})$$

$$= \frac{\gamma}{\gamma + \rho} (u(q) - c(q) + V_{0}), \tag{47}$$

which yields

$$V_0 = \frac{\gamma}{\rho}(u(q) - c(q)). \tag{48}$$

This is analogous to the lifetime utility under a PS that employs a gift-giving game in the discrete-time version of the model presented in the text. In the absence of settlement costs, equation (48) also gives the lifetime expected payoff of an incentive feasible PS that decentralizes transactions of size q.

When costly settlement occurs after each time length T, it involves an aggregate (average) fixed cost δ . Hence, the net present value of the settlement costs is given by

$$\sum_{n=1}^{\infty} e^{-n\rho T} \delta = \delta \frac{e^{-\rho T}}{1 - e^{-\rho T}}.$$
(49)

Thus, the continuous-time version of the value function, V_0 , is given by

$$V_0 = \frac{\gamma}{\rho} (u(q) - c(q)) - \delta \frac{e^{-\rho T}}{1 - e^{-\rho T}}.$$
 (50)

As before, we define the PS adjustments conditional on the agents' reports by

$$pK_t - c(q) = pL_t = pB_t, (51)$$

for all t. Also, since the PS is repeated, we have that adjustments, X, satisfy

$$X_{nT+t} = Xe^{\rho(T-t)},\tag{52}$$

for all $t \in [nT; (n+1)T]$, where n is an integer. As in the discrete-time case, such a PS implies that all IC are fulfilled. In addition, it satisfies all PC for the largest set of parameter values. Next, we derive the market clearing condition for the settlement stage. This is accomplished by approximating total balance adjustments in an interval of length T. First, note that the probability of having exactly n arrivals of trading opportunities in the interval [0, t] is given by

$$P[N_t = n] = e^{-\gamma t} \frac{(\gamma t)^n}{n!}.$$
(53)

For small Δ , we then have that

$$P[N_{\Delta} = 1] \approx \gamma \Delta,\tag{54}$$

where $P[N_{\Delta} > 1] = o(\Delta)$. Next, define $\Delta = \frac{T}{m}$, where $m \in [0, T]$ is an integer. The total adjustment for producers over an interval of length T is then approximately given by

$$\gamma \Delta K_{\Delta} + \dots + \gamma \Delta K_{(m-1)\Delta} + \gamma \Delta K_{m\Delta}
= \gamma \Delta K \left[e^{\rho(T-\Delta)} + \dots + e^{\rho(T-(m-1)\Delta)} + e^{\rho(T-m\Delta)} \right]
= \gamma \Delta K e^{\rho T} \left[\frac{1 - \left(e^{-\rho \Delta} \right)^m}{1 - e^{-\rho \Delta}} - 1 \right]
= \gamma K \left[\frac{\Delta e^{\rho(T-\Delta)} - \Delta}{1 - e^{-\rho \Delta}} \right].$$
(55)

As $\Delta \to 0$, an agent will almost surely receive at most one opportunity to trade during a time length Δ . In that case, using L'Hôpital's rule,²³ the expected total adjustments to producers are given by $\frac{\gamma}{\rho}K\left(e^{\rho T}-1\right)$. The expected total balance adjustments to consumers are similarly determined and given by $\frac{\gamma}{\rho}L\left(e^{\rho T}-1\right)$. Finally, expected balance adjustments for all agents who have received no trading opportunities over this time interval can be determined as follows. For each interval of length Δ , a measure $2\gamma\Delta$ of agents are engaged in transactions ($\gamma\Delta$ of them as consumers and $\gamma\Delta$ as producers). Therefore, the measure of agents who are not involved in any transactions over an interval of length Δ is $(1-2\gamma)\Delta$.

 $^{^{23}}$ Note that both the numerator and the denominator in this expression go to zero. In addition, we have $\lim_{\Delta \to 0} \frac{f'(x)}{g'(x)} = \lim_{\Delta \to 0} \frac{-\Delta \rho e^{\rho(T-\Delta)} + e^{\rho(T-\Delta)} - 1}{\rho e^{\rho\Delta}} = \lim_{\Delta \to 0} -\Delta e^{\rho T} + \frac{e^{\rho T}}{\rho} - \frac{1}{\rho e^{-\rho\Delta}} = \frac{1}{\rho} (e^{\rho T} - 1).$

As a result, the aggregate balance adjustments for non-trading activities over the interval of length T are given by

$$(1 - 2\gamma) \Delta B_{\Delta} + \dots + (1 - 2\gamma) \Delta B_{(m-1)\Delta} + (1 - 2\gamma) \Delta B_{m\Delta}$$

$$= \frac{(1 - 2\gamma)}{\rho} B\left(e^{\rho T} - 1\right). \tag{56}$$

Market clearing during the settlement stage is then given by the following equation:

$$\frac{1}{\rho} \left(e^{\rho T} - 1 \right) \left[\gamma p K + \gamma p L + (1 - 2\gamma) p B \right] = -\delta. \tag{57}$$

Using the above balance adjustments, one obtains

$$pB = -\delta \rho \frac{1}{e^{\rho T} - 1} - \gamma c(q). \tag{58}$$

The worst possible balance adjustment is assigned to agents that either never traded or never produced in the interval [0,T]. Following the above discussion, this adjustment is given by $\frac{1}{\rho} \left(1 - e^{-\rho T}\right) pB$. This implies that the only PC that is potentially binding is given by

$$\frac{1}{\rho} \left(e^{\rho T} - 1 \right) pB + \frac{\gamma}{\rho} (u(q) - c(q)) - \delta \frac{e^{-\rho T}}{1 - e^{-\rho T}} \ge 0.$$
 (59)

This constraint is identical to the one in the discrete-time version, simply adjusting for the continuous time discount factor. Given these adjustments, an optimal PS chooses q and T in order to solve the following maximization problem:

$$\max_{q,T} \frac{\gamma}{\rho} (u(q) - c(q)) - \delta \frac{e^{-\rho T}}{1 - e^{-\rho T}}$$
subject to
$$\frac{1}{\rho} \left(e^{\rho T} - 1 \right) pB + \frac{\gamma}{\rho} (u(q) - c(q)) - \delta \frac{e^{-\rho T}}{1 - e^{-\rho T}} \ge 0,$$

$$pB = -\delta \rho \frac{1}{e^{\rho T} - 1} - \gamma c(q).$$
(60)

The objective function expresses the discounted lifetime utility of a representative participant. The second constraint summarizes the PC that is potentially binding, while the third constraint summarizes the IC and the market clearing conditions that must be satisfied in any incentive feasible PS. The equality in the last equation follows from the fact that the PS works for the largest set of parameters if it makes all IC exactly bind. The constraint set can be rewritten to obtain

$$\frac{\gamma}{\rho} \left[u(q) - e^{\rho T} c(q) \right] \ge \delta \frac{1}{1 - e^{-\rho T}},\tag{61}$$

or

$$(1 - e^{-\rho T}) u(q) - (e^{\rho T} - 1) c(q) \ge \frac{\rho}{\gamma} \delta.$$
(62)

The objective function is strictly concave in (q, T). In order to guarantee that the constraint set is convex, we need an additional assumption. Given any T (q), the function on the left-hand side of the above inequality is concave in q (T). However, the left-hand side is not necessarily jointly concave in (q, T) due to the second term, which is a product of two convex functions. We have the following sufficient condition for the constraint set to be convex.²⁴

Lemma 8. Suppose that c(q) is log-convex. Then $e^{\rho T}c(q)$ is a strictly convex function in (q,T), and the constraint set is convex.

Proof. A function is log-convex if its natural logarithm is convex. Since c(q) is log-convex, we have that

$$\frac{\partial^2 \ln c(q)}{\partial q^2} = \frac{c(q)c''(q) - (c'(q))^2}{(c(q))^2} > 0.$$
 (63)

The first term of the LHS in equation (61) is strictly concave in q, while the RHS is strictly convex in T. The remaining term has a Hessian given by

$$H(q,T) = \begin{pmatrix} \rho^2 e^{\rho T} c(q) & \rho e^{\rho T} c'(q) \\ \rho e^{\rho T} c'(q) & e^{\rho T} c''(q) \end{pmatrix}. \tag{64}$$

The first principal minor is positive, while the second principal minor is positive if and only if

$$c(q)c''(q) - (c'(q))^2 > 0.$$
 (65)

Hence, since c(q) is log-convex, $e^{\rho T}c(q)$ is convex. The result follows, since the sum of two concave functions is concave.

²⁴A weaker condition is given by $-\frac{1}{e^{\rho T}}u''(q)c(q) \ge c'^2 - c''(q)c(q)$.

Taking first-order conditions with respect to q and T, we obtain the following characterization of the solution:

$$\frac{u'(q) - c'(q)}{c'(q)} = \frac{\lambda}{1 + \lambda} \left(e^{\rho T} - 1 \right), \text{ and}$$
 (66)

$$\frac{\delta}{c(q)} \frac{\rho}{\gamma} \left(\frac{1}{e^{\rho T} - 1} \right) = \frac{\lambda}{1 + \lambda} \left(e^{\rho T} - 1 \right), \tag{67}$$

where λ is the multiplier on the single constraint. This leads us to the following.

Lemma 9. Let c(q) be log-convex. For any optimal PS with settlement, we have $\hat{q} < q^*$.

Proof. Since δ , γ , and ρ are positive, and the optimal settlement length is finite $(\hat{T} \in (0, \infty))$, we must have that $\lambda > 0$. Hence, equation (66) implies that $u'(\hat{q}) - c'(\hat{q}) > 0$. Since c is increasing and strictly convex, and u is increasing and strictly concave, this implies that $\hat{q} < q^*$.

Eliminating λ from the first-order conditions (66) and (67), we obtain a single first-order condition

$$\frac{\gamma}{\rho} \frac{u'(q) - c'(q)}{c'(q)} \left(e^{\rho T} - 1 \right) = \frac{\delta}{c(q)}. \tag{68}$$

This condition, together with the constraint (61), characterizes the solution (\hat{q}, \hat{T}) . Solving these equations yields the optimal length of the transaction stage, \hat{T} , as a function of ρ and \hat{q} ; i.e.,

$$\frac{u(q)}{u'(q)}\frac{c'(q)}{c(q)} = e^{\rho T}. (69)$$

The optimal transaction size, \hat{q} , is given by

$$u(q)\left(1 - \frac{c'(q)}{u'(q)}\right) + c(q)\left(1 - \frac{u'(q)}{c'(q)}\right) = \delta\frac{\rho}{\gamma}.$$
 (70)

A solution to the last equation exists by the Intermediate-Value-Theorem. Furthermore, any solution must lie in an interval $[\underline{q}, q^*]$, where $\underline{q} > 0$. The problem is that the left-hand side of equation (70) is non-monotonic. Hence, there will, in general, be more than one solution to this equation. The optimal solution, however, corresponds to the one closest to (and below) q^* . The next Proposition relies solely on the fact that at this solution, \hat{q} , the left-hand side of equation (70) is locally strictly decreasing.

Lemma 10. Assume that c(q) is log-convex. As the settlement cost, δ , increases, the optimal transaction size, \hat{q} , as well as the optimal length of the transaction stage, \hat{T} , decreases.

Proof. We establish first that \hat{q} and \hat{T} move in the same direction; i.e. $\frac{d\hat{T}}{d\hat{q}} > 0$. Differentiating the left-hand side of equation (69) with respect to q, we obtain

$$\frac{1}{(u'(q)c(q))^2} \left[u(q)u'(q) \left(c(q)c''(q) - (c'(q))^2 \right) + c(q)c'(q) \left((u'(q))^2 - u(q)u''(q) \right) \right], \tag{71}$$

which is strictly positive, as u is strictly increasing and strictly concave, while c is log-convex.

Next, we show that \hat{q} is decreasing in δ . Denote the left-hand side of equation (70) by $\Gamma(q)$. Differentiating $\Gamma(q)$ with respect to q and collecting terms we obtain

$$\frac{\partial\Gamma}{\partial q} = c''(q) \left[\frac{c(q)}{c'(q)} \frac{u'(q)}{c'(q)} - \frac{u(q)}{u'(q)} \right] + u''(q) \left[\frac{c'(q)}{u'(q)} \frac{u(q)}{u'(q)} - \frac{c(q)}{c'(q)} \right]. \tag{72}$$

We can rewrite equation (70) as

$$\frac{\gamma}{\rho} \frac{u'(q) - c'(q)}{c'(q)} \left(\frac{u(q)}{u'(q)} \frac{c'(q)}{c(q)} - 1 \right) = \frac{\delta}{c(q)}. \tag{73}$$

Since u'(q) > c'(q), for $q < q^*$, we obtain that $\frac{u(q)}{u'(q)} > \frac{c(q)}{c'(q)}$. Letting $q \to q^*$, this implies that

$$\frac{c(q)}{c'(q)}\frac{u'(q)}{c'(q)} - \frac{u(q)}{u'(q)} < 0, (74)$$

and

$$\frac{c'(q)}{u'(q)}\frac{u(q)}{u'(q)} - \frac{c(q)}{c'(q)} > 0. \tag{75}$$

Hence, $\frac{\partial \Gamma}{\partial q} < 0$, or, equivalently, the left-hand side of equation (70) is strictly decreasing for q sufficiently close to q^* . Furthermore, $\Gamma(q)$ converges to 0 as $q \to q^*$. Hence, $\Gamma(q) > 0$ for q sufficiently close to q^* and, by the continuity of $\Gamma(q)$, there must exist a solution to equation (70) for small enough $\delta > 0$. Finally, since $\Gamma(q) \downarrow 0$ as $q \to q^*$, we must have that $\Gamma'(\hat{q}) \leq 0$ (with Γ having possibly a local maximum at \hat{q}). This completes the proof.
