Abstract

We examine the impact of incomplete risk-sharing on growth and welfare. The source of market incompleteness in our economy is private information: a household’s idiosyncratic productivity shock is not observable by others. Risk-sharing between households occurs through long-term contracts with intermediaries. We find that incomplete risk-sharing tends to reduce the rate of growth relative to the complete risk-sharing benchmark. Numerical examples indicate that the welfare cost and the growth effect of private information are small.
1. Introduction

Recent research has found evidence that is inconsistent with the full insurance predictions of the complete markets model. For example, Cochrane (1991), Mace (1991) and Hayashi et al. (1996) provide evidence against complete risk-sharing within the U.S. at the individual level; Townsend (1994) and Maitra (1997) reject full insurance across households within Indian villages; and Backus et al. (1992), Baxter and Crucini (1995) and Athanasoulis and van Wincoop (1997) provide evidence against cross-country consumption risk-sharing. Motivated by this finding, we consider the effect of risk on growth and welfare. We develop an environment where household production is subject to idiosyncratic shocks that are private information, and growth is endogenous. The assumption of private information provides a basis for market incompleteness; the resulting problem of incentive compatibility eliminates the possibility of complete risk-sharing. Households share risk through long-term contracts with competitive intermediaries. The enduring relationship allows intermediaries to exploit intertemporal trade-offs, thereby providing (partial) insurance.

Previous work on risk and growth typically has contrasted complete risk-sharing with autarchy. Since the extent of market incompleteness is endogenous in our environment, we are able to examine an intermediate case. We find that the presence of uninsurable risk reduces the rate of growth relative to the complete risk-sharing benchmark. This, for example, differs from the result in Devereux and Smith (1994). Comparing autarchy with complete risk-sharing, in a model
of capital risk that essentially shares our technology and preferences, they find that the effect of risk on savings, and hence growth, is ambiguous.\footnote{The ambiguous effect of risk on savings was noted by Levhari and Srinivasan (1969). Specifically, when the elasticity of intertemporal substitution is low (high), risk tends to raise (reduce) savings. (See also Weil (1990).) Obstfeld (1994) shows that when risk-sharing leads to a portfolio shift into riskier, more productive assets, it may be growth promoting.} Our results indicate that the impact of risk on growth and welfare is likely to be sensitive to the origin of market incompleteness and the types of insurance arrangements allowed.

In related work, Marcet and Marimon (1992) examine a two-agent model with capital accumulation where a risk-neutral investor with unlimited resources invests in the technology of a risk-averse producer whose output is subject to productivity shocks that are private information.\footnote{See also Aiyagari and Williamson (1997) for a model of credit in which only the social planner has access to capital.} Our work extends their analysis to a market-clearing economy with endogenous growth. In contrast to Marcet and Marimon, we find that investment, as well as consumption, is affected by shocks to production. As a result, there are growth effects of private information. However, numerical examples indicate that, on average, the growth and welfare effects of incomplete risk-sharing are likely to be small.

In section 2 we describe technology, preferences, and the contract. Section 3 solves the contract assuming logarithmic utility, while section B of the appendix examines the contract when utility is iso-elastic. Numerical examples are presented in section 4; these provide quantitative measures of the size of the growth and welfare effects resulting from private information. Section 5 discusses additional applications of our model. In particular, there are several interesting
differences between our long-term contracting economy with production and the more standard model of contracts with risky endowments. These may be of independent interest.

2. The Environment

In each period, there is a large number of households each of which operates a technology of the form \( Y_t = z_t K_t \) where \( Y_t \) is output, \( K_t \) is capital, and \( z_t \) is the level of productivity at time \( t = 0, 1, \ldots \). Productivity, which is independently and identically distributed across households at any time and over time for any household, takes on one of two possible values: it is \( z_i \) with probability \( \mu_i > 0 \), \( i = 1, 2 \), where \( 0 < z_1 < z_2 \) and \( \mu_1 + \mu_2 = 1 \). We define the expected value of productivity as \( \xi = \sum_{i=1}^{2} \mu_i z_i \) and assume that capital completely depreciates after production.

Households are infinitely lived and possess time separable preferences over sequences of consumption with period utility from current consumption, \( C \), of the form

\[
v(C) = \begin{cases} 
(1 - \beta) \frac{C^{1-\sigma}}{1-\sigma} & \text{for } \sigma > 0 \text{ and } \sigma \neq 1, \\
(1 - \beta) \log C & \text{for } \sigma = 1.
\end{cases}
\]

Note that, for convenience, we normalize the utility function by \( (1 - \beta) \in (0, 1) \) where future utility is discounted by \( \beta \).

Each household participates in a permanent contract with a risk-neutral, competitive intermediary. As we will characterize the solution to the contract using
a functional approach, we find it useful to provide a recursive description of the timing of events within the contractual arrangement here.\footnote{However, a formal statement of the contractual arrangement as a sequence problem is contained in the Technical Appendix.} In any period, only the household observes its own productivity, thus there is private information with respect to output. At the beginning of the period the household has a predetermined capital stock, $K$. Given the household’s capital, the intermediary announces a set of potential transfers, $B_i$, and investments, $K'_i$, as functions of the impending productivity report. Upon observing its output, $z_iK$, the household determines a report for the intermediary. Subsequently, the intermediary executes the transfer and implements the investment for the household, which determines its capital stock at the onset of the next period. By definition, if the contract is incentive-compatible, then, at every point in time, the household will truthfully report the level of productivity. Hence, the household’s consumption in state $i$ will be $C_i = z_iK + B_i$ and its investment will be $K'_i$.

As is evident from above, the intermediary observes the household’s investment but not its consumption. The intermediary can borrow from, or lend to, other intermediaries at a competitive interest rate. This yields a constant discount factor, $q \in (0, 1)$, that is determined by equilibrium conditions.

In the initial period, a large number of intermediaries compete to establish permanent contracts with households. As a result of perfect competition, intermediaries’ initial expected discounted profits for each contract are driven to zero; consequently, each household accepts a contractual arrangement that yields it the highest feasible level of lifetime utility.

Our approach to solving the contract adapts the methods used to characterize
the risky endowment model of long-term contracts.\footnote{See for example Green (1987), Taub (1990), Phelan and Townsend (1991), Atkeson and Lucas (1992) and the related analysis of Spear and Srivastava (1987) and Thomas and Worrall (1990).} An important assumption in extending the existing results to our analysis is that the household has no ability to invest in an unobservable manner. The value of misreporting productivity lies in being able to consume hidden output. A parable may be helpful. Let the stock of capital represent trees and let the fruit of these trees be consumed or planted to yield fruit-bearing trees for the next period. Our assumption on the observability of investment is equivalent to assuming that the intermediary is able to observe the quantity of trees, at any point in time, but not the yield per tree. A household may hide output, fruit, from the intermediary. This hidden fruit may be consumed without being detected. However, if the household chooses to plant any of it, then it is observable, in the form of trees, in the next period. This allows the intermediary to infer the household’s deception.

In order to ensure truth-telling (incentive-compatibility), we constrain the contract so there are no gains from one-period temporary deviations from truth-telling. That is, the contract is temporarily incentive compatible (t.i.c.) in the sense of Green (1987). Provided certain boundary conditions, satisfied by our problem, hold, temporary incentive compatibility is equivalent to incentive compatibility. Next, since the t.i.c. constraints introduce future expected lifetime utility as a state variable, we follow Green in characterizing the contract by solving a dual, expenditure minimization problem for the intermediary. Standard duality theorems ensure that this solution also solves the utility maximization problem faced by the household.\footnote{Proofs of these results are contained in the Technical Appendix.} Finally, we impose an aggregate resource con-
straint upon our economy: the sum of consumption and investment cannot exceed output. This is related to the approach taken by Atkeson and Lucas (1992) in the context of an endowment economy. However, in contrast to their work, we solve for equilibrium, not efficient, allocations.

Let $U_i'$ represent expected lifetime utility, starting next period, for the household, assuming that it will accurately report productivity from that date onward, given a current productivity report of $z_i$. When the state is $z_1$, temporary incentive compatibility is ensured by the following constraint.

$$\text{if } z_1 K + B_2 > 0 \text{ then } v(z_1 K + B_1) + \beta U_1' \geq v(z_1 K + B_2) + \beta U_2' \quad (2.1)$$

The left hand side of the second inequality in (2.1) represents the value to the household with actual output $z_1 K$ of truthfully reporting its productivity. Provided that misreporting the level of productivity generates a feasible level of consumption, then the right hand side of this constraint represents the value of following this strategy. The $t.i.c.$ constraint when productivity is $z_2$ is given below.

$$v(z_2 K + B_2) + \beta U_2' \geq v(z_2 K + B_1) + \beta U_1' \quad (2.2)$$

Note that, as $z_2 > z_1$, non-negativity of $C_1$ ensures that $z_2 K + B_1 \geq 0$, eliminating the need for a conditional constraint. As discussed in Oh and Green (1992), concavity of $v$ implies that if both (2.1) and (2.2) are to hold, then $B_1 \geq B_2$ and $U_1' \leq U_2'$. Furthermore, if (2.2) binds and $B_1 \geq B_2$ ($B_1 > B_2$) then (2.1) is satisfied (holds with inequality). These results will prove useful below.

As indicated earlier, we obtain equilibrium allocations for the contracting economy using a dual approach. Given an initial utility entitlement, $U$, and capital
stock, $K$, for the household, the intermediary solves an expenditure minimization problem. Hereafter, we will refer to the solution of the expenditure minimization problem as the contract. In this formulation, we must impose a promise-keeping constraint upon the contract, which ensures that the household’s expected lifetime utility satisfies its initial entitlement.

$$U \leq \sum_{i=1}^{2} \mu_i \left( v(z_i K + B_i) + \beta U_i' \right)$$ \hspace{1cm} (2.3)

Let the expected present value of expenditure be $E(U, K)$. Recall that the intermediary discounts future expenditures by $q$. The contract, which minimizes the intermediary’s net expenditure, by choice of $(B_i, K'_i, U'_i)_{i=1}^{2}$, subject to the incentive compatibility constraints (2.1) - (2.2) and the promise-keeping constraint (2.3), satisfies the following Bellman equation.

$$E(U, K) = \min \sum_{i=1}^{2} \mu_i \left( B_i + K'_i + qE(U'_i, K'_i) \right)$$ \hspace{1cm} (2.4)

The expected present value of expenditure, at the optimum, will equal the sum of expected current expenditure and the discounted expected present value of expenditures incurred from the next period onwards.

A competitive intermediary must maximize the household’s expected lifetime utility; in equilibrium, this implies an initial level of expected lifetime utility, $U_0$, given the household’s starting stock of capital, $K_0$, such that the zero profit condition $E(U_0, K_0) = 0$ is satisfied. This zero profit condition is required only at the beginning of each long-term contractual arrangement. As competition between intermediaries is for permanent contracts with households, we cannot impose this
condition in subsequent periods. However, we will establish the result that, in
equilibrium, the intermediary’s expected profits are indeed zero in every period.

3. Analysis

In this section we provide a complete characterization of the private information
economy for the case of logarithmic preferences. The case of general iso-elastic
utility is similar and is summarized in section B of the appendix.

3.1. The Contract

In order to solve the Bellman equation, we deflate the value function by capital.
This allows us to reformulate the contract in an intensive form which, by exploiting
a homogeneity property of the constraint correspondence that describes the set
of feasible allocations, reduces the dimension of the state vector. Let \( b_i K = B_i \)
and \( \gamma_i K = K'_i \) for \( i = 1, 2 \). Rewrite the objective as

\[
E(U, K)/K = \min \sum_{i=1}^{2} \mu_i \left( b_i + \gamma_i + q \gamma_i E(U'_i, K'_i)/K'_i \right).
\] (3.1)

Now define a composite state variable, \( u \equiv U - \log K \). Consistency requires that
the future state, conditional on \( i \), is given by \( u'_i = U'_i - \log K'_i \). Since this implies
that \( U'_i = u'_i + \log \gamma_i + \log K \), the t.i.c. constraint at \( z_1 \) may be revised as

\[
\text{if } z_1 + b_2 \geq 0 \text{ then } (1 - \beta) \log (z_1 + b_1) + \beta (u'_1 + \log \gamma_1) \geq (1 - \beta) \log (z_1 + b_2) + \beta (u'_2 + \log \gamma_2),
\] (3.2)
while the t.i.c. constraint at $z_2$ is equivalent to

$$(1 - \beta) \log (z_2 + b_2) + \beta \left( u_2' + \log \gamma_2 \right) \geq (1 - \beta) \log (z_2 + b_1) + \beta \left( u_1' + \log \gamma_1 \right).$$

(3.3)

Subtracting $\log K$ from both sides of (2.3), the promise-keeping constraint becomes

$$u \leq \sum_{i=1}^{2} \mu_i \left( (1 - \beta) \log (z_i + b_i) + \beta \left( u_i' + \log \gamma_i \right) \right).$$

(3.4)

Since the constraints above depend only upon the composite state variable, we are able to define $W(u) = E(U, K)/K$. The intensive form problem, which describes expenditures per unit capital, satisfies the following Bellman equation.

$$W(u) = \min \sum_{i=1}^{2} \mu_i \left( b_i + \gamma_i + q\gamma_i W(u_i') \right)$$

(3.5)

where the minimization is with respect to $(b_i, \gamma_i, u_i')_{i=1}^2$.

We now analyze the intensive form contract. Let $\lambda$ and $\theta$ be the multipliers for the constraints (3.3) and (3.4). We suppress (3.2) which never binds, as is shown below in proposition 3.1. The first order conditions, with respect to $(b_i, \gamma_i, u_i')_{i=1}^2$, are listed below.\textsuperscript{6}

\textsuperscript{6}Standard results imply that the value function is strictly increasing, convex, and differentiable. See Stokey et al (1989).
The Benveniste-Scheinkman theorem implies $W(\mu) = \theta$.

Conditions (3.6) - (3.11) allow a strong characterization of the risk-sharing contract. First, the introduction of productive capital offers a channel for adjusting utility entitlements absent in the endowment model. The linear production structure implies that utility entitlements, $U$, are linear functions of the logarithm of the capital stock, $K$. As a result, the continuation value of the state variable, $u_0$, is independent of productivity and the initial state, $u$. Changes in expected lifetime utility that occur in response to productivity reports are implemented through changes in the household’s stock of capital. Second, risk-aversion on part of the household implies that the contract insures current consumption: when the household reports low productivity the net transfer is higher than when it reports high productivity ($b_1 > b_2$). Alternatively, repayment is lower. However, the presence of private information limits the extent of risk-sharing. Households must be prevented from under-reporting income during periods when income is relatively high. As a result, reports of low productivity reduce lifetime consump-
tion. Given diminishing marginal utility, the cost-minimizing intermediary will spread this fall in lifetime consumption over time. Consequently, our third result is that low productivity results in both lower current consumption and reduced investment \((c_1 < c_2 \text{ and } \gamma_1 < \gamma_2)\). These qualitative characteristics of the contract are summarized in the following proposition. (All proofs are in Appendix A.)

**Proposition 3.1.** In the log case, \(u_1' = u_2', \gamma_1 < \gamma_2, b_1 > b_2 \text{ and } c_1 < c_2\).

The higher transfer when \(z = z_1\), given the binding incentive constraint at \(z_2\), implies that the t.i.c. constraint at \(z_1\) does not bind, as assumed above.

### 3.2. Equilibrium

As noted earlier, since \(E\) is strictly increasing in \(U\) given \(K\), the zero profit condition \(E(U, K) = 0\) will determine the highest level of (initial) expected lifetime utility feasible for the household given its (initial) stock of capital, \(K\). Since \(E(U, K) = KW(U - \log K)\), this zero profit condition implies \(W(u) = 0\). Given strict monotonicity of \(W\), this pins down \(u\) and implies that \(U\) is proportional to \(\log K\). Hence \(u\) and the contract \((b_i, \gamma_i, u_i')_{i=1}^2\) are the same for all households.

As a result, any household with capital stock \(K\) and productivity \(z_i\) will be allocated current consumption \((z_i + b_i)K\) and investment \(\gamma_iK\). Average output for all households with \(K\) units of capital will be \(\xi K\), assuming a positive measure of such households; average consumption for this group will be \(\sum_{i=1}^2 \mu_i (z_i + b_i)K\) and average investment will be \(\sum_{i=1}^2 \mu_i \gamma_i K\).

Economy-wide market clearing requires that aggregate output equal the sum of aggregate consumption and investment. Let \(\psi(K)\) represent the distribution
of capital across households over the space of current capital holdings, $K$. Equilibrium requires that

$$
\int_K \xi K \psi(K) = \int_K \left( \sum_{i=1}^2 \mu_i (z_i + b_i + \gamma_i) \right) K \psi(K).
$$

This market-clearing condition implies that $\sum_{i=1}^2 \mu_i (b_i + \gamma_i) = 0$. Next, using (3.5), we have the result, $W(u) = \sum_{i=1}^2 \mu_i q \gamma_i W(u_i)$. Recalling $u_1' = u_2'$ and $W(u) = 0$, this implies $W(u_i') = W(u) = 0$, $i = 1, 2$. Thus, $u_i' = u$, $i = 1, 2$, and $E(U, K) = 0$ in all states along the equilibrium path. This establishes the important result that zero expected profits are a period by period feature of our risk-sharing agreement. Hence the initial zero-profit condition is sustained over time in the equilibrium contract.

Finally, (3.8) and (3.10) yield the equilibrium condition $q \theta = 1$. Note that the recursive equilibrium is stationary in the sense that $(b_i, \gamma_i)_{i=1}^2$, $q$ and $u$ are time-invariant. This verifies our earlier conjecture that $q$ is constant.

We now contrast growth between our incomplete risk-sharing economy and the complete risk-sharing benchmark. The latter, a well-known problem, may be retrieved by suppressing (3.3) (setting $\lambda = 0$ everywhere) and repeating the above analysis. The solution, denoted by superscript $f$, is characterized by $c_i^f = (1 - \beta) \xi$ and $\gamma_i^f = \beta \xi$ for $i = 1, 2$. Furthermore, under complete risk-sharing $q^f \xi = 1$ and $u_i^f = \log (1 - \beta) \left( \beta \xi \right)^{1/(1 - \beta)}$.

The introduction of private information reduces the mean rate of growth, $\sum_{i=1}^2 \mu_i \gamma_i$, relative to the complete risk-sharing value of $\beta \xi$. As a result, the intermediary’s discount rate, $q^{-1} - 1$, falls. We suggest the following explanation. If, upon observing $z_2$, the household truthfully reports productivity, then it con-
sumes $C_2$, while misrepresentation yields consumption equal to $(z_2 - z_1) K + C_1$. All else being equal, higher levels of capital tend to increase the current gains to deviations from truth-telling. The contract then requires larger variations in both $C_i$ and $U_i'$ in order to ensure incentive-compatibility. Given convexity of preferences, this tends to reduce welfare for any given level of resources. This welfare reducing aspect of additional capital makes investment less attractive in the private information economy relative to the complete risk-sharing economy. Hence the overall rate of capital accumulation is lower under private information.

**Proposition 3.2.** In equilibrium, $q > \xi^{-1}$ and $\sum_{i=1}^{2} \mu_i \gamma_i < \beta \xi$.

We calculate the expected increase in lifetime utility as $\sum_{i=1}^{2} \mu_i (U_i' - U) = \sum_{i=1}^{2} \mu_i \log \gamma_i$. Proposition 3.2 and Jensen’s Inequality jointly imply that the expected increase in welfare is lower under private information. However, this does not imply that welfare has a negative trend leading to the immiserization of almost all households. This result, due to the possibility of economic growth, is in sharp contrast to the endowment model. Since we cannot assume that the equilibrium allocation is efficient, it is important to emphasize that the lack of a negative trend may not characterize the efficient allocation.

4. Numerical examples

We examine several numerical examples. These allow us to describe the risk-sharing arrangement in more detail and obtain preliminary evidence on the magnitude of the growth and welfare effects of the incomplete risk-sharing environment. The baseline parameter values we use are in table 1. The average level of productivity is set equal to the long-run return on equity in the U.S., $\xi = 1.065$, as
indicated in Mehra and Prescott (1985). We allow productivity to vary symmetrically around its mean. Thus we assume that $\mu_1 = 0.5$ and $x = \xi - z_1 = z_2 - \xi$. The parameter $x$ is difficult to calibrate. In our baseline case we set its value to imply that the coefficient of variation of $z$ is 0.1. This value implies a standard deviation of consumption growth of 0.0468, which is close to 0.044 predicted by the base case of Heaton and Lucas (1996, table 4, p.458).\footnote{Below, we will examine examples involving different values of $x$.} Finally we choose $\beta$ so that $\beta \xi = 1.02$. The aggregate rate of growth for the complete risk-sharing economy, when household preferences are logarithmic, matches the long-run growth data, as documented in Parente and Prescott (1993). This is also the average rate of growth under autarchy and, as we shall see, not significantly different from the rate of growth under incomplete risk-sharing.

We first examine the case of logarithmic preferences. Across the three different allocations, autarchy ($A$), incomplete risk-sharing ($I$), and complete risk-sharing ($C$), $u + \log K$ represents the level of expected lifetime utility for a household with capital $K$. Thus $u$ is the expected lifetime utility for a household with one unit of capital. Each entry in the rows of tables 2 through 5 marked loss represents the percentage decrease necessary in the level of consumption under complete risk-sharing, at every point in time, to match the level of welfare associated with the other economies. We deflate all quantity variables by the level of capital. Thus, given a shock $z_i$, the household’s savings is $-b_i$ and $c_i$ is consumption, per unit capital. Investment per unit capital is denoted $\gamma_i$, which is also the gross rate of growth of capital. The average rate of growth is denoted $E(\gamma)$, while $r$ is the percentage discount rate ($q = \frac{1}{1+r}$). Finally, $\Delta U$ represents the expected increase in lifetime utility.
In table 2 we see that, in the complete risk-sharing allocation, consumption and investment are unresponsive to the productivity shock. The household’s savings varies with productivity so as to completely smooth the consumption profile. The incomplete risk-sharing economy induces fluctuations in current consumption, but this variability in consumption is low relative to that under autarchy. There is a net transfer of resources from households with high current productivity to those with low current productivity: \(c_1 + \gamma_1 > z_1\) while \(c_2 + \gamma_2 < z_2\). For those experiencing below average productivity, this reduces savings while boosting both consumption and investment, relative to autarchy. The residual variability in consumption, and the reduced average growth rate, causes expected welfare to increase more slowly than under complete risk-sharing, \(\Delta U = 0.0184 < 0.0198\). The inability to smooth consumption under autarchy implies high variability in both consumption and investment rates. Consequently, welfare increases yet more slowly, \(\Delta U = 0.0148\).

In figure 1, we illustrate initial expected lifetime utility for the complete risk-sharing, incomplete risk-sharing, and autarchy economies. As indicated by the loss measures in table 2, the move from complete to incomplete insurance is equivalent to a 1.6% decrease in the level of consumption, while autarchy implies an 11.2% decrease. In this example, we see that incentive-compatible arrangements are relatively successful in smoothing consumption. The switch from such an economy to autarchy results in a significant loss in expected utility, measured in units of full insurance consumption, for the typical household.

In figures 2 and 3 we graph the evolution of the distribution of capital (\(K\)), deflated by the compounded growth factor and expected lifetime utility (\(U\)) for the incomplete risk-sharing economy. All households are initially identical. Recall
that the intermediary enforces truth-telling by offering relatively higher lifetime utility entitlements for high productivity reports than for low productivity reports at each point in time. As a result, both distributions of wealth and utility are characterized by increasing dispersion over time. For this example, the distribution of utility entitlements within each period is symmetric. Convexity of preferences then implies a skewed distribution of capital. In proposition 3.1 we showed that, in the private information economy, changes in welfare are implemented through changes in capital. This log-linear mapping is also, of course, present in the autarchic model. The greater variability in investment present in autarchy implies that the private information economy dampens dispersion over time relative to autarchy.

Next, in table 3, maintaining our other baseline parameters, we allow the coefficient of relative risk aversion, \( \sigma \), to vary between \( \frac{1}{2} \) and 4. We find that the rate of growth under private information is consistently below the complete risk-sharing equivalent. This result, which we have found to be robust, indicates that the growth-reducing effect of incomplete risk-sharing, found for logarithmic preferences, extends to the case of iso-elastic utility. Interestingly, both the growth and welfare effects of private information fall as \( \sigma \) rises. Recall that higher values of \( \sigma \) are associated with increased reluctance to substitute consumption across time. As shown in proposition 3.1, potential deviations from truth-telling raise current consumption at the expense of future consumption. As \( \sigma \) increases, the attractiveness of such behaviour is reduced. This reduces the costs of private information and shifts the incomplete risk-sharing allocation closer to full insurance. For all \( \sigma \), the contract is relatively efficient. Even when the intertemporal elasticity of substitution is high (\( \sigma = 0.5 \)), the loss is only 2.57%. Note that, for
the same \( \sigma \), the loss under autarchy is more than three times as large, 9.77%.

For higher values of \( \sigma \), autarchy yields larger welfare losses relative to incomplete risk-sharing. Furthermore, under autarchy, income uncertainty generates a strong motive to self-insure through savings when risk aversion is large. This drives the high rates of growth relative to complete risk-sharing. As is well known, the sign of the risk effect on savings changes when \( \sigma \) crosses one. In contrast, the growth rate under incomplete risk-sharing is always below that under complete risk-sharing, and the growth effects are small.

In table 4, we vary the coefficient of variation of \( z \). This implies changes in \( z_1 \) and \( z_2 \). All other parameters are maintained at the values listed in table 1. Higher variability of productivity implies higher risk and tends to reduce both growth and welfare under private information. However, the differences in rates of growth never rise above one-tenth of one percent, and the associated welfare loss is small relative to autarchy. Table 5 considers changes in the discount factor, \( \beta \), while maintaining all other parameters at the table 1 values. The three discount factors we consider, \( \beta = 0.9390, 0.9577, \) and 0.9765 imply 0, 2, and 4 per cent average growth, respectively. Note that higher values of \( \beta \) imply an increased emphasis on future consumption. As indicated by the negative trend in loss, the welfare cost of private information decreases.

These numerical examples indicate that, across a range of parameter values, (1) the growth effects of incomplete risk-sharing are small and (2) the incomplete markets economy achieves levels of welfare close to the levels attained under complete risk-sharing. The relative efficiency of the private information economy arises from the ability to adjust capital, and hence output, in response to the changes necessary in lifetime utility entitlement over time. This implies that changes in
a household’s utility entitlement are matched by proportionate movements in the
gain from understating productivity, \((z_2 - z_1) K\).

5. Concluding remarks

We have examined the impact of incomplete risk-sharing on growth and welfare in
an environment with private information. In our economy, households share risk
by entering into enduring relationships with competitive intermediaries. We have
found that the aggregate growth rate is lower under private information than un-
der full insurance. Furthermore, the risk-sharing arrangement, while incomplete,
is relatively efficient and the growth effects of private information are generally
small.

Our work adapts the methods used to study long-term contracting with risky,
unobservable endowments to an economy with production and capital accumu-
lation. The contract with capital exhibits several properties that contrast with
the standard model.\(^8\) First, expected lifetime utility, while growing more slowly
than under complete risk-sharing, does not necessarily contain a negative trend.
Second, the contract exhibits the property that all changes in welfare are imple-
mented through changes in the household’s stock of capital. Consequently, welfare
always exceeds the autarchy value of capital. Finally, while both the endowment
and production economies share the property that the distribution of wealth or
utility entitlements is characterized by increasing dispersion, in the production

---

\(^8\)Examples, already mentioned above, include Green (1987) and the equilibrium model of
Atkeson and Lucas (1992). As noted earlier, the properties that distinguish our model of risk-
sharing with production and capital accumulation may not hold in efficient allocations.
economy this rising inequality is larger under autarchy.\textsuperscript{9}

The contract implements risk-sharing by conditioning the household’s future lifetime utility, or wealth, on the current report of productivity. Thus we emphasize the problem of unobservable returns to investment, the common emphasis of the literature on private information in development economics. If investment were itself unobservable, then our risk-sharing arrangement would be infeasible.\textsuperscript{10} In particular, the intermediary cannot exploit differences in the rates of intertemporal substitution across households. It is, however, unclear what types of risk-sharing arrangements are then feasible. We view this as an area for future research.

An implication of our findings is that if resources may be devoted towards either (1) reducing the effects of informational asymmetries and thereby implementing improved insurance services (allowing for observable returns to investment), or (2) developing the legal basis for implementing state-contingent enforceable contracts (allowing for observable investment), such as those we have assumed, then expenditures on the latter may be far more important for welfare gains.

\textsuperscript{9}See Aiyagari and Alvarez (1996) for an interesting example of an endowment economy where lower bounds on the consumption possibilities set ensure that the economy is characterized by an invariant distribution of wealth.

\textsuperscript{10}See Cole and Kocherlakota (1997) for an economy with risky endowments and unobservable storage, where the rate of return to storage is exogenous.
Appendix

A. Proofs

Proof of Proposition 3.1:

We divide the proof into 5 parts.

1) \( u_1' = u_2' = u' \): Equations (3.8) and (3.10) jointly imply that \( 1 + q W(u_1') = q W'(u_1') \) while (3.9) and (3.11) together yield \( 1 + q W(u_2') = q W'(u_2') \). Thus we see that \( u_1' = u_2' \) and this common value, labeled \( u' \) is independent of \( u \) and thus common to all contracts.

2) \( \lambda > 0 \): (By contradiction) Given part (1), assume that \( \lambda = 0 \). Next, from (3.8) and (3.9) we have \( \gamma_1 = \gamma_2 \) while (3.6) and (3.7) yield \( z_1 + b_1 = z_2 + b_2 \). Since this implies that \( z_2 + b_1 > z_2 + b_2 \) we have violated (3.3).

3) \( \gamma_1 < \gamma_2 \): Given parts (1) and (2), we may solve (3.10) and (3.11) to obtain

\[
\gamma_1 = \beta \frac{\theta - \frac{\lambda}{W'(u')}}{\theta} < \beta \frac{\theta + \frac{\lambda}{W(u')}}{qW'(u')} = \gamma_2.
\]

4) \( b_1 > b_2 \): Given parts (1) - (3), we know that \( \beta \log \gamma_2 - \beta \log \gamma_1 > 0 \) which requires that \( (1 - \beta) (\log (z_2 + b_2) - \log (z_2 + b_1)) < 0 \) for (3.3) to hold with equality.

5) \( c_1 = z_1 + b_1 < z_2 + b_2 = c_2 \): Given part (2), rearranging (3.6) and (3.7) we have

\[
\mu_1 \left( 1 - \frac{\theta(1-\beta)}{z_1 + b_1} \right) = -\frac{\lambda(1-\beta)}{z_2 + b_1} < 0 \quad \text{while} \quad \mu_2 \left( 1 - \frac{\theta(1-\beta)}{z_2 + b_2} \right) = \frac{\lambda(1-\beta)}{z_2 + b_2} > 0.
\]

This requires that \( z_1 + b_1 < z_2 + b_2 \).

Proof of Proposition 3.2:

As \( W'(u') = \theta \) and \( q \theta = 1 \), (3.10) and (3.11) may be solved as \( \gamma_1 = \theta \beta - \frac{\lambda \beta}{\mu_1} \) and \( \gamma_2 = \theta \beta + \frac{\lambda \beta}{\mu_2} \). Next (3.6) and (3.7) may be rearranged as
\[
\begin{align*}
\mu_1 (z_1 + b_1) + \lambda (1 - \beta) \frac{z_1 + b_1}{z_2 + b_1} &= \mu_1 \theta (1 - \beta) \\
\mu_2 (z_2 + b_2) - \lambda (1 - \beta) &= \mu_2 \theta (1 - \beta).
\end{align*}
\]

It then follows that

\[
\sum_{i=1}^{2} \mu_i (b_i + \gamma_i) - \lambda (1 - \beta) \left[1 - \frac{z_1 + b_1}{z_2 + b_1}\right] = \theta - \xi.
\]

Given proposition 3.1, we know that \(\lambda > 0\), so that, as \(z_1 < z_2\), we know that \(\lambda (1 - \beta) \left[1 - \frac{z_1 + b_1}{z_2 + b_1}\right] > 0\). Recalling the equilibrium condition \(\sum_{i=1}^{2} \mu_i (b_i + \gamma_i) = 0\), we have proven \(\theta < \xi\). Therefore \(q \xi > 1\) and \(\sum_{i=1}^{2} \mu_i \gamma_i = \beta \theta < \beta \xi\). ■

B. Iso-elastic preferences

We solve the iso-elastic case, drawing heavily on the analysis of section 3. The intensive form composite state variable for this case is given by \(u = \frac{\nu}{\kappa^{\sigma}}\). The contract is determined by solving (3.5) subject to (B.1) - (B.3).

\[
\begin{align*}
\text{if } z_1 + b_2 & \geq 0 \text{ then } (1 - \beta) \left(\frac{z_1 + b_1}{1 - \sigma}\right) + \beta \gamma_1^{1-\sigma} u_1' \\
& \geq (1 - \beta) \left(\frac{z_1 + b_2}{1 - \sigma}\right) + \beta \gamma_2^{1-\sigma} u_2' \\
(1 - \beta) \left(\frac{z_2 + b_2}{1 - \sigma}\right) + \beta \gamma_2^{1-\sigma} u_2' & \geq (1 - \beta) \left(\frac{z_2 + b_1}{1 - \sigma}\right) + \beta \gamma_1^{1-\sigma} u_1' 
\end{align*}
\]
\[ u \leq \sum_{i=1}^{2} \mu_i \left[ (1 - \beta) \frac{(z_i + b_i)^{1-\sigma}}{1-\sigma} + \beta \gamma_i^{1-\sigma} u_i' \right] \]  
(B.3)

Suppressing (B.1) which, as before, does not bind, defining \( \lambda \) to be the multiplier for (B.2) and \( \theta \) the multiplier for (B.3), we derive the following efficiency conditions with respect to \( (b_i, \gamma_i, u_i')_{i=1}^{2} \).

\[
\begin{align*}
\mu_1 + \lambda_1 (1 - \beta) (z_1 + b_1)^{-\sigma} - \mu_1 \theta (1 - \beta) (z_1 + b_1)^{-\sigma} &= 0 \quad (B.4) \\
\mu_2 - \lambda_1 (1 - \beta) (z_2 + b_2)^{-\sigma} - \mu_2 \theta (1 - \beta) (z_2 + b_2)^{-\sigma} &= 0 \quad (B.5) \\
\mu_1 \left( 1 + qW (u_1') \right) + \lambda_1 \beta \gamma_1^{1-\sigma} (1 - \sigma) u_1' - \mu_1 \theta \beta \gamma_1^{1-\sigma} (1 - \sigma) u_1' &= 0 \quad (B.6) \\
\mu_2 \left( 1 + qW (u_2') \right) - \lambda_1 \beta \gamma_2^{1-\sigma} (1 - \sigma) u_2' - \mu_2 \theta \beta \gamma_2^{1-\sigma} (1 - \sigma) u_2' &= 0 \quad (B.7) \\
\mu_1 q \gamma_1 W' (u_1') + \lambda_1 \beta \gamma_1^{1-\sigma} - \mu_1 \theta \beta \gamma_1^{1-\sigma} &= 0 \quad (B.8) \\
\mu_2 q \gamma_2 W' (u_2') - \lambda_1 \beta \gamma_2^{1-\sigma} - \mu_2 \theta \beta \gamma_2^{1-\sigma} &= 0 \quad (B.9)
\end{align*}
\]

It is straightforward to show that proposition 3.1 holds for the general iso-elastic case. Furthermore, equilibrium in the economy with iso-elastic preferences may be calculated using the method described in section 3.2. An examination of the growth effects of private information given iso-elastic utility, which requires numerical methods, is contained in table 3 and discussed in section 4.

Technical Appendix

A. The Contractual Arrangement

In this appendix, we develop two standard results on incentive compatibility and duality that allow us to solve the contract using a recursive dual approach. We reiterate some of the exposition of the text below, in the interest of completeness.

Let $z_t$ describe an individual’s productivity at time $t = 0, 1, \ldots$. Productivity is independently and identically distributed over time and across individuals. Specifically, $z_t \in Z = \{z_1, z_2\}$ where $0 < z_1 < z_2$. Let $\mathcal{Z} \equiv 2^Z$ be the complete $\sigma$-algebra and define $\mu : \mathcal{Z} \to [0, 1]$ as a probability measure on $\mathcal{Z}$, summarized by $\mu(z_i) = \mu_i > 0$. The contract requires that the agent report his productivity in each period. A reporting strategy is $\sigma = (\sigma_0, \sigma_1, \ldots)$ such that $\sigma_t : Z^{t+1} \to Z$ is the time $t$ report of productivity by the agent. Let $\Sigma$ represent the set of all measurable reporting strategies.

In each period, the intermediary will assign the agent both a transfer for current consumption and investment for future production. Let $B_t(\sigma_t) : Z^{t+1} \to \mathbb{R}$ be the net transfer to the agent as a function of his reported history of productivity shocks and $K_{t+1}(\sigma_t) : Z^{t+1} \to \mathbb{R}_+$ be investment in the agent’s technology for the next period. Output at time $t$ is $z_tK_t(\sigma_t−1)$ and consumption at time $t$ is $C_t(z_t, \sigma_t) = z_tK_t(\sigma_t−1) + B_t(\sigma_t)$. We adopt the convention that $\sigma^{-1} = \emptyset$ and $K_0(\sigma^{-1}) = K_0 \in \mathbb{R}_+$ is given. A plan is a sequence of vector-valued functions $(K, B)$, where $K = \{K_t\}_{t=0}^{\infty}$ and $B = \{B_t\}_{t=0}^{\infty}$, which allows for a feasible level of consumption at every point in time, in every state of nature: $z_tK_t(z_t^{t−1}) + B_t(z_t^t) \geq 0, \forall z_t^t \in Z^{t+1}, t = 0, 1, \ldots$. Let $\Pi(K_0)$ be the set of all
plans and let $\Sigma(K, B) \subseteq \Sigma$ be the set of all measurable reporting strategies which allow for feasible consumption given a plan $(K, B) \in \Pi(K_0)$.

The agent has a strictly increasing and continuous von Neumann-Morgenstern period utility function $v : \mathbb{R}_+ \to \mathbb{R}$ and subjective discount factor $\beta \in (0, 1)$. The expected lifetime utility from a plan $(K, B) \in \Pi(K_0)$ and a reporting strategy $\sigma \in \Sigma(K, B)$ is denoted $V(K, B, \sigma)$.

$$V(K, B, \sigma) = \sum_{s=0}^{\infty} \beta^s \int_{Z^{s+1}} v\left(z_s K_s \left[\sigma_{s+1}^{-1}(z_{s+1})\right] + B_s [\sigma^s(z^s)]\right) \mu^{s+1}(dz^s).$$

A plan $(K, B) \in \Pi(K_0)$ is incentive compatible if it offers the agent a level of expected lifetime utility, when he reports each period’s productivity accurately, that is no less than the level of utility from any other reporting strategy:

$$V(K, B, z) \geq V(K, B, \sigma), \ \forall \sigma \in \Sigma(K, B). \quad (A.1)$$

As we shall see, the intermediary’s expenditures will be discounted at some constant rate $q^{-1} - 1$. Under this assumption, let $E_0(K, B)$ be the discounted cost implied by the plan $(K, B) \in \Pi(K_0)$:

$$E_0(K, B) \equiv \sum_{s=0}^{\infty} q^s \int_{Z^{s+1}} [K_{s+1}(z^s) + B_s(z^s)] \mu^{s+1}(dz^s). \quad (A.2)$$

\footnote{The probability space $(Z, \mathcal{Z}, \mu)$ generates the finite dimensional product probability spaces $(Z^t, \mathcal{Z}^t, \mu^t)$, $t = 0, 1, \ldots$, as well as the infinite dimensional probability space of all measurable sequences of technology shocks $(Z^\infty, \mathcal{Z}^\infty, \mu^\infty)$ in the standard manner.}
**Definition A.1.** The contract between an intermediary and an agent is the solution to the following problem: given $K_0$, maximize $V(K, B, z)$ over the set of all plans $(K, B) \in \Pi(K_0)$ satisfying the incentive compatibility constraint (A.1) and the financial constraint $E_0(K, B) \leq 0$.

Let the value of the optimum, be denoted $V^*(K_0)$.

**A.1. temporary incentive compatibility**

Having defined incentive compatibility, we now develop the well known equivalent, temporary incentive compatibility. This will allow us to characterize a solution to the contract using a recursive approach. Below, we define temporary incentive compatibility constraints and prove their equivalence to incentive compatibility for the above contract. Our proof draws heavily on the work of Green (1987); we adapt his techniques to an environment with investment.

Given a plan $(K, B) \in \Pi(K_0)$, and the reporting of a partial history $z^{t-1} \in Z^t$, we define the expected value of truthful future reporting as

$$V(K, B, z; z^{t-1}) = \sum_{s=t}^{\infty} \beta^{s-t} \int_{Z^{s+1-t}} v \left( z_s K_s \left[ z_{s+1-t} z^{s-1} \right] + B_s \left[ z_{s+1-t} z^{s} \right] \right) \mu^{s+1-t}(dz^s)$$

where note that $\mu^k = \mu^k \times \mu$.12 Given (A.3), preferences will satisfy

12If $s \geq t$ then $z^s = (z_t, z_{t+1}, \ldots, z_s) \in Z^{s-t+1}$, otherwise $z^s = \emptyset$. 

3
\[ V(K, B, z; z^{t-1}) = \int_Z \left[ v \left( z_t K_t[z^{t-1}] + B_t[z^{t-1}, z_i] \right) + \beta V \left( K, B, z; [z^{t-1}, z_i] \right) \right] \mu(dz_t). \] (A.4)

A plan is \((z, t)\)–incentive compatible (i.c.) if having reported, \(z^{t-1}\) through date \(t-1\) the agent has no incentive to misrepresent future productivity. Formally, a plan \((K, B)\) is \((z, t)\)–i.c. if

\[ V(K, B, z; z^{t-1}) = \max_{\{\sigma \in \Sigma(K, B) \mid \sigma^{t-1}(z^{t-1}) = z^{t-1}\}} V(K, B, \sigma; z^{t-1}). \] (A.5)

Note that incentive compatibility is equivalent to \((z, 0)\)-incentive compatibility. If the agent has reported productivity \(z^{t-1}\) through date \(t - 1\) and is constrained to truthfully report productivity from date \(t + 1\), we define a plan to be \((z, t)\)–temporarily incentive compatible (t.i.c.) if it provides no incentives for misrepresentation of \(z_t\).

A plan \((K, B)\) is \((z, t)\)–t.i.c. if given \(z_i, z_j \in Z\) with \(j \neq i\),

\[
\begin{align*}
&v \left( z_i K_t(z^{t-1}) + B_t(z^{t-1}, z_i) \right) + \beta V \left( K, B, z; [z^{t-1}, z_i] \right) \\
&\geq v \left( z_i K_t(z^{t-1}) + B_t(z^{t-1}, z_j) \right) + \beta V \left( K, B, z; [z^{t-1}, z_j] \right).
\end{align*}
\] (A.6)

The first result proves the equivalence of current incentive compatibility and current temporary incentive compatibility given incentive compatibility next period.

**Lemma A.2.** The plan \((K, B) \in \Pi(K_0)\) is \((z, t)\)–i.c. if and only if it is \((z, t)\)–t.i.c. and \((z, t+1)\)–i.c.
Proof. \( \Rightarrow \) Let \((K, B)\) be a plan that is \((z, t)\)-i.c. and assume that it is not \((z, t+1)\)-i.c. Then there exists \(\sigma_a \in \Sigma(K, B)\) such that \(\sigma_a(z^t) = z^t\), \(\forall z^t \in \mathbb{Z}^{t+1}\) and \(V(K, B, \sigma_a; z^t) > V(K, B, z, \tilde{z}^t)\) for some \(\tilde{z}^t \in \mathbb{Z}^{t+1}\). Consider the plan \(\sigma_b\) where \(\sigma_b^s(z^s) = z^s\) for \(s = 0, 1, \ldots, t\) and \(\sigma_b^s(z^s) = z^s\) \(\forall s \geq t + 1\) unless \(z^s = [(\tilde{z}_0, \ldots, \tilde{z}_{t+1}) z^s] \) for any \(t+1 z^s \in \mathbb{Z}^{t+1}\). In this case, let \(\sigma_b^s(z^s) = \sigma_a^s(z^s)\). Equation (A.4) implies that \(V(K, B, \sigma_b; z^{t-1}) > V(K, B, z, z^{t-1})\) contradicting \((z, t)\)-i.c. of \((K, B)\). Alternatively, assume that \((K, B)\) is not \((z, t)\)-t.i.c., then for some \(z_i \in \mathbb{Z}\), (A.6) fails. Given (A.4), this contradicts (A.5).

\( \Leftarrow \) If \((K, B)\) is a plan that is both \((z, t)\)-t.i.c. and \((z, t+1)\)-i.c., then (A.4) immediately establishes (A.5).

Using this result, and assuming that a plan \((K, B)\) satisfies the boundary condition

\[
\lim_{t \to \infty} \beta^t V(K, B, z; z^t) = 0, \forall z \in \mathbb{Z}^\infty, \quad (A.7)
\]

we are able to prove that incentive compatibility is equivalent to temporary incentive compatibility. Towards proving this stronger result, it is useful to rewrite (A.3) as

\[
V(K, B, z; z^{t-1}) =
\sum_{s=t}^{n-1} \beta^{s-t} \int_{\mathbb{Z}^{s+1-t}} v \left(z_s K_s \left[z^{t-1}_{s,t} z^s\right] + B_s \left[z^{t-1}_{s,t} z^s\right]\right) \mu^{s+1-t}(d_t z^s)
\]

\[
+ \int_{\mathbb{Z}^{n+1-t}} \beta^{n-t} V(K, B, z; z^{t-1}_{n,t} z^n) \mu^{n+1-t}(d_t z^n). \quad (A.8)
\]
Lemma A.3. Given (A.7) holds, the plan \((K, B)\) is \((z, 0) - \text{i.c.}\) if and only if it is \((z, t) - \text{t.i.c.}\) for all \(t = 0, 1, \ldots\).

Proof. \((\Rightarrow)\) Repeated applications of lemma A.2 proves that if \((K, B)\) is \((z, t) - \text{i.c.}\) then it is \((z, t) - \text{i.c.}\) for \(t = 0, 1, \ldots\).

\((\Leftarrow)\) Let \((K, B)\) be \((z, t) - \text{t.i.c.}\) for all \(t = 0, 1, \ldots\), but assume that it is not \((z, 0) - \text{i.c.}\). Then there exists \(\tilde{\sigma} \in \Sigma(K, B)\) such that \(\epsilon = V(K, B, \tilde{\sigma}) - V(K, B, z) > 0\). Given (A.7) and (A.8), \(\exists n \in \mathbb{N}\) such that \(V(K, B, \tilde{\sigma}) > V(K, B, z)\) where \(\tilde{\sigma}^t(z^t) = \tilde{\sigma}^t(z^t)\) for \(t < n\) and \(\tilde{\sigma}_t(z^t) = z_t\) for \(t \geq n\). This strategy involves misrepresentation at only a finite number of nodes, a maximum of \(n^2\). Let \(z^l \in \mathbb{Z}^{l+1}\) describe the last node at which there is misrepresentation. As \((K, B)\) is \(t.i.c.\) at \(z^l\), truth-telling dominates any other strategy. We see that \(\tilde{\sigma}\) allows for misrepresentation at a maximum of \((n - 1)^2\) nodes. Backwards induction proves that \(\tilde{\sigma}\) is \((z, 0) - \text{i.c.}\).

A.2. duality

We now develop a duality result similar to that in Green (1987) and Oh and Green (1992). The dual expenditure minimization problem examined below will be shown to be equivalent, given the appropriate initial condition, to the utility maximization problem solved in the contract. Given this result, we will exploit the simplicity of the dual approach to help us characterize the contract. In the dual problem, allocations are constrained so that the agent receives some predetermined level of expected lifetime utility entitlement, which we denote \(V^*\).

\[ V(K, B, z) \geq V^*. \quad (A.9) \]
Given this level of utility, the dual involves the minimization of expenditure by the intermediary.

**Definition A.4.** The dual contract minimizes $E_0(K, B)$ subject to $(K, B) \in \Pi(K_0)$ satisfying (A.1) and (A.9).

Define the value of the optimum as $E^*(V^*, K_0)$. Our duality result, which is standard, states that if $(K^*, B^*)$ solves the contract and the value of the optimum is $V^*(K_0)$, then given $V^*(K_0)$, $(K^*, B^*)$ solves the dual problem. Furthermore, if $(\hat{K}, \hat{B}) \in \Pi(K_0)$ solves the dual problem given $V^*(K_0)$, then $V(\hat{K}, \hat{B}, z) = V^*(K_0)$ and $(\hat{K}, \hat{B})$ solves the contract.

**Lemma A.5.** Let $(K^*, B^*) \in \Pi(K_0)$ solve the contract and define $V^* = V(K^*, B^*, z)$, then $(K^*, B^*)$ solves the dual contract. Furthermore, if there exists $(\hat{K}, \hat{B}) \in \Pi(K_0)$ that also solves the dual contract, then $(\hat{K}, \hat{B})$ solves the contract.

**Proof.** ($\Rightarrow$) Since $(K^*, B^*)$ solves the contract, it satisfies (A.1), (A.9) and $E_0(K^*, B^*) \leq 0$ by definition. Assume there exists $(\hat{K}, \hat{B}) \in \Pi(K_0)$ which also satisfies (A.1) and (A.9) where $\varepsilon \equiv E_0(K^*, B^*) - E_0(\hat{K}, \hat{B}) > 0$. As $(\hat{K}, \hat{B})$ satisfies (A.1), it is $(z, 0)$-i.c. which by lemma A.2 implies that it is $(z, 0)$ – t.i.c. and $(z, 1)$–i.c.. For (A.6) to hold for both $i = 1, 2$, given concavity of $v$, it must be true that $B_0(z_1) \geq B_0(z_2)$. Next, temporary incentive compatibility for $i = 2$, requires $V(K, B, z, z_1) \leq V(K, B, z, z_2)$. There are three possibilities: (a) equation (A.6) does not bind for either $i = 1$ or $2$, (b) equation (A.6) binds only for $i = 1$ or 2, or (c) equation (A.6) binds for both $i = 1$ and $i = 2$. We design an alternative plan $(\hat{K}, \hat{B})$ for each case. Let $\overline{\alpha}(z^t) = \hat{B}_t(z^t)$ for all $t > 0$ and $\overline{\alpha}(z^t) = \hat{K}_t(z^t)$.
for all \( t \). If temporary incentive compatibility for \((\hat{K}, \hat{B})\) is characterized by (a), then let \( \bar{B}_0(z_i) > \hat{B}_0(z_i) \) for either \( i = 1 \) or 2 until (A.6) binds for either \( i \) or \( \bar{B}_0(z_i) = \hat{B}_0(z_i) + \varepsilon \). Alternatively if case (b) applies, let \( \bar{B}_0(z_i) > \hat{B}_0(z_i) \) until the t.i.c. for \( j \neq i \) binds or \( \bar{B}_0(z_i) = \hat{B}_0(z_i) + \varepsilon \). If case (c) applies then it must be true that \( \hat{B}_0(z_1) = \hat{B}_0(z_2) \); let \( \bar{B}_0(z_i) = \hat{B}_0(z_i) + \varepsilon/2 \). In each case, the alternate plan \((\hat{K}, \hat{B})\) is temporary incentive compatible at \( t = 0 \) and, by construction, \((z, 1) - i.c.\), thus it satisfies (A.1). Furthermore, \( E_0(\hat{K}, \hat{B}) \leq 0 \) and \( V(\hat{K}, \hat{B}, z) > V^*(K_0) \). This contradicts the assumption that \((K^*, B^*)\) solves the contract.

\((\Leftarrow)\) Next assume that \((\hat{K}, \hat{B})\) solves the dual problem, but not the primal. Since \((\hat{K}, \hat{B}) \in \Pi(K_0)\) by definition, and satisfies both (A.1) and (A.9), then it must be that \( E_0(\hat{K}, \hat{B}) > 0 \geq E_0(K^*, B^*) \). This contradicts the assumption that \((\hat{K}, \hat{B})\) solves the dual. \(\blacksquare\)

The equivalence of solving the contracting problem described in definition A.1 and the expenditure minimization problem described in section 2 follows from lemmas A.3 and A.5.
